INDEX TO VOL. LXXI

OF

“THE INDIAN MEDICAL GAZETTE”

For the year 1936

[Original Article 'O.A.'; Mirror of Hospital Practice 'H.P.'; Editorial 'E.'; Special Article 'S.A.'; Medical News 'M.N.'; Commentaries 'Com.'; Current Topics 'C.T.'; Correspondence 'C.'; *Italics* signify Reviews; Reviews are placed under the name of the author; they also appear under the heading 'Reviews', where they are arranged according to subjects.]

	Page		Page		Page
A		Allen, F. R. W. K. A Case of Malignant Tumour of the Stomach in a Male with Transposition of the Viscera (H. P.)	32	Ansari, M. A. <i>Regeneration in Man</i>	298
<i>A. subpictus</i> Grassi (<i>A. rossi</i> 'Type' Giles), Abstract of a Paper on Experimental Malarial Infection of (Strickland and Roy) (O. A.)	327	— F. R. W. K. Treatment of Syphilis by Modenol (O. A.)	329	Anti-Cholera Inoculation, Late Reactions after (Epidemic Medical Officer) (C.)	691
Abraham, A. C. <i>see</i> Chenoy, C. F. and Siddiqui, M. A. Investigation of Yaws in Warangal (O. A.)	322	— F. R. W. K., and Dave, M. L. The Treatment of Rhinosporidiosis in Man based on the Study of Sixty Cases (O. A.)	376	— Inoculation, Late Reactions after (Tewari) (C.)	242
Acharjee, K. K. Training in Pharmacy in India (C.)	118	Ammonium Mandelate, Mandelic Acid and, in the Treatment of Urinary Infections (Holling and Platt) (C. T.)	538	— Inoculations, Reaction after (Banerjee) (C.)	562
Acharya, B. G. S., and Jaswal, J. N. <i>Ætiology</i> of Primary Glaucoma (O. A.)	582	Amœbiasis and Appendicitis (Banerji, Chopra and Ray) (O. A.)	693	Antill, J. M. <i>The Emancipist: An Historical Drama in Three Acts</i>	677
Acne Vulgaris, Observations on the Treatment of (Michael) (C. T.)	415	— Results and Dangers in the Treatment of, A Summary of Fifteen Years' Clinical Experience at the Mayo Clinic (Brown) (C. T.)	287	Anti-Malarial Remedies on Monkey Malaria, Studies on the Action of (Chopra, Ganguly and Roy) (O. A.)	443
Adenoides Cysticum, Epithelioma (Goyle, Krishnaswami and Vasudevan) (O. A.)	74	Amœbic Dysentery in 1933, The Chicago Outbreak of (C. T.)	741	Anti-Rabic Treatment, A Case of Paraplegia and Hydrophobia following a Full Course of (Sen Gupta) (H. P.)	660
<i>Aedes aegypti</i> (<i>Stegomyia fasciata</i>), Mosquito Breeding in Country Craft, A Practical Way of dealing with (Bana) (O. A.)	79	Anæmia, Hæmorrhage and, in the Newborn (Lightwood) (C. T.)	161	Antiseptic Properties of Raw Cod-Liver Oil (Bose) (C.)	627
Agranulocytosis, Report on a Fatal Case of (Das Gupta) (H. P.)	589	Anæmias, The Classification of the (Napier) (S. A.)	343	Antiseptics and Coagulants in Composting Habitation Wastes, The Utility of (Nicholson and Chakrabarty) (O. A.)	717
Alcohol, Intravenous Injections of, The Treatment of Lobar Pneumonia with (Mittra) (C.)	118	— of Nutritional Deficiency, <i>Ætiology</i> , Diagnosis, Treatment and Prevention (Minot) (C. T.)	102	Appendicitis, Amœbiasis and (Banerji, Chopra and Ray) (O. A.)	693
— Intravenous, in Pneumonia (De) (H. P.)	276	— Pernicious and other Macrocytic (Davidson) (C. T.)	479	Appendix, Three Cases of Adherent Retrocæcal (Chopra) (H. P.)	467
— The Treatment of Lobar Pneumonia with Intravenous Injections of (Bradford) (C.)	178	Anæsthesia, Oxygen, Nitrous Oxide and, for Major Surgery (Madan) (S. A.)	533	<i>Appleton-Century Company. The Practitioners' Library of Medicine and Surgery, Vol. IX, 1936</i>	549
Alexander Memorial Prize (M. N.)	537	Anderson, E. W. Treatment of the Neuroses (C. T.)	667	— <i>Company, The Practitioners' Library of Medicine and Surgery, Vol. X, 1936</i>	550
All-India Medical Conference, XIII (M. N.)	663	Annual Conference for Medical Officers in Industry Overseas (M. N.)	347	Apte, V. Y. A Case of Persistent Hiccup (H. P.)	464
— Medical Licentiate's Association, Bombay (M. N.)	348	Anophelines in India, The Species Control of (Ramsay and Macdonald) (O. A.)	699	Arabian Desert, Heat Exhaustion and Dehydration in the (Stott) (O. A.)	712
— Medical Licentiate's Association (M. N.)	410				
— Obstetric and Gynaecological Congress, Second, Bombay (M. N.)	535				
— Ophthalmological Conference (M. N.)	406

THE FEEDING OF INFANTS IN INDIA

By E. H. VERE HODGE, M.D. (Cantab.)

M.R.C.P. (Lond.)

LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine, First Physician, Medical College Hospitals, Calcutta

ARTIFICIAL FEEDING

THERE comes a period in the lives of most babies in India, as in other countries, when natural food must be abandoned.

Before embarking on the delicate task of changing from natural to artificial feeding, the mother or attendant must have a clear plan outlined and the following matters are for decision :

1. The choice of food.
2. The method of preparation.
3. The amount of food required in the 24 hours.
4. The capacity of the child's stomach, that is to say, the size of each feed.
5. The optimum interval between each feed.

Choice of food.—The best substitute is fresh cow's milk, modified or diluted according to the digestive capacities and needs of the infant. Cow's milk must conform to certain standards. It must be clean, for there are many sources of contamination, the milker's hands, dirty vessels, vessels washed with polluted water, dirty udders of the cow. The danger of transmitting tuberculosis from an infected cow to the infant is a real one and it must be remembered that a high proportion of the tuberculosis of infancy is bovine and may be attributed to milk-borne infection, though this danger in India is not so great as in England. Dirty milk, even if boiled, is still dirty, and the swarms of dead bacteria may set up intestinal irritation. In India today, owing to the difficulty in obtaining milk up to standard, dried milks such as Cow and Gate or Glaxo are extensively used with excellent results.

Of the physical properties, the fat content is most liable to variation. A series of analyses kindly supplied by Lieut.-Colonel A. D. Stewart shows that the fat content of the milk of individual cows varies as widely as from 3.7 to 6.9 and that in the cold weather the figure is generally higher. It is desirable, therefore, that the fat content of the milk chosen should be known.

The milk must have a good vitamin content. This will depend on the surroundings and feeding of the cow. The effect of feeding and sun-

light on the vitamin content of milk have peculiar application and importance in India. The vitamin content is poor when the cow is fed on dried fodder as it is in the plains in India in the hot weather. The sources of suitable supply are available in India. In large centres there are well run dairies under careful supervision, supplying milk of standard quality. There are those who prefer to keep a private cow, in which case the welfare of the animal must be carefully guarded. The cow should be inspected periodically by a veterinary officer.

Goat's milk.—In many parts of India, the milk of goats is used with success as a substitute for cow's milk. The goat is easily kept in the compound, and milked under supervision, but special care must be taken to frustrate its natural tendency to promiscuous feeding. The animal being less subject to tuberculosis than the cow, the milk may be given unboiled should circumstances demand.

The milk has approximately the same proportionate contents as cow's milk and is used in the same way, modified or diluted to suit the individual.

It will, of course, not be used where there is any suspicion of the existence of undulant fever.

The question now arises as to the form in which the milk is to be administered. For the healthy child there are three methods of feeding with cow's milk, the whole milk method, the method of adding water in gradually decreasing proportions according to the supposed digestive capacity of the child and, finally, the method of physiological feeding advocated by Dr. Eric Pritchard and many other pædiatristians, the proportions in the feed being brought as near to that of human milk as is possible.

Whole-milk feeding.—There are still advocates of the whole-milk method; their advocacy is based on two not very convincing grounds; the first, that it is impossible, by any form of modification, to produce a substitute really comparable to human milk, and the second, that the majority of infants do well, and that those who do not, must be placed in the category of delicate or difficult infants. It is true that many infants rise to the occasion and manage to thrive in spite of this rather drastic method, but in India the infant has much to contend with, and we cannot afford to add to his burden for we do not really know how far the seeds of disease in later life may be sown in early infancy by incorrect feeding. The graver defects will produce immediate results such as rickets and indigestion, but, of the more remote effects, it is not possible to speak definitely. This being the case, we are not in a position to take liberties with the nutrition and digestion, and a food cannot be pronounced absolutely satisfactory merely because there is no immediate protest.

Two methods therefore remain, the first, the method of dilution, whereby the protein content

is reduced to a figure within the digestive capacity of the infant, the fat is reduced, and the sugar is brought up to or higher than the original content by the addition of sugar of milk or cane sugar. This method is suitable for the hot weather.

The second, of which the aim is to so modify the milk by dilution and additions, that the composition approximates as nearly as possible to breast milk. This method gives excellent results in temperate climates and is suitable to hill stations and the cold weather of the North, but must not be attempted in the hot weather. On the contrary we must definitely abandon all idea of feeding babies according to European standards and should regard the proportions as protein 2, fat not more than 2 and carbohydrate 6 to 8 as being suitable, there being a lowered tolerance to fat and increased tolerance to carbohydrate provided that part is given as dextri-maltose, *e.g.*, Mellin's food.

The amount of food required.—The amount may be calculated in one or two ways. The first, by multiplying the weight of the child in pounds by a figure varying from $1\frac{1}{4}$ to $2\frac{1}{2}$ according to the prevailing temperature

TABLE I
According to weight (Patterson)

Weight of infant in pounds	Ounces of cow's milk	Ounces of water	Tea-spoons of sugar	Number of feeds
5	7	6	5	6
6	8 $\frac{1}{2}$	6	6	6
7	11 $\frac{1}{2}$	6	7	6
8	13	7	8	6
9	15	8	9	6
10	17	8	10	5
11	19	9	11	5
12	21	9	12	5
13	22	9	13	5
14	23	10	14	5
15	24	10	15	5

The figures given represent the requirements for 24 hours. In using the above table care should be taken that the infant is not receiving too high a quantity of fat, and should the milk be obviously rich, some portion should be skimmed off.

High dilutions in the early weeks, with gradual progress towards whole milk as the digestive capacity increases, are indicated.

TABLE II

According to age

Age	Dilution	Number of feeds in 24 hours	Quantity per feed	Average quantity of diluted milk in 24 hours	Quantity of sugar to be added to each feed	Quantity of cream to be added	Hours of feeding	
			oz.	oz.	Teaspoon	Teaspoon	a.m.	p.m.
2 to 7 days ..	1 to 3	8	1 to 2	10	$\frac{1}{4}$..	6. 9.	12 3. 6.
1 month ..	1 to 2	6	2 to 4	20	$\frac{1}{2}$	$\frac{1}{4}$	do.	do.
2 months ..	1 to 1 $\frac{1}{2}$	6	3 to 4	27	$\frac{3}{4}$	$\frac{1}{2}$	do.	do.
3 months ..	1 to 1	6	4 to 5	32	1	$\frac{3}{4}$	do.	do.
4 to 5 months ..	1 to $\frac{3}{4}$	6	5 to 6	35	1 $\frac{1}{4}$	1	do.	do.
6 to 7 months ..	1 to $\frac{1}{2}$	5	6 to 7	38	1 $\frac{1}{2}$	1	6. 10	2. 6. 10
8 to 9 months ..	pure	5	7 to 8	40	1 $\frac{1}{2}$	1	do.	do.

of the atmosphere. The resulting figure will give approximately the number of ounces of breast milk or its equivalent required in the 24 hours. A simple method of calculation for the hot weather is after the figures of Hess, namely, that a baby requires $1\frac{1}{2}$ ounces of milk, one ounce of water and $1/10$ ounce of sugar for every pound of body weight. It is important to note that though the food requirements go down as the temperature of the atmosphere is raised, the requirements of fluid are increased so that the baby will require three ounces of fluid or more for each pound of body weight. The following tables will serve as a guide:—

HUMANIZED MILK.

Method 2.—The principle of this method is that we follow the instructions of nature and endeavour so to modify cow's milk that it may approximate in composition as nearly as possible to human milk. In practice this method has been found to be satisfactory but its use must be limited to temperate or winter climates. At first sight the imitation of human milk is simple. By diluting the milk till the proportion of proteid is that of human milk and then adding cream and sugar, we have what is known as humanized milk. Humanizing is a comfortable term, but it must not be forgotten that,

humanized milk is not identical with human milk.

Preparation

	oz.
Cow's milk of good average quality ..	10
Cream, 33 per cent (this is the average cream obtained by centrifugalization) ..	1
Sugar ..	1
Water to ..	20

The composition of this mixture is as follows:—

Protein, 1.75 per cent; carbohydrate, 7 per cent; fat, 3.5 per cent.

TABLE III

Average requirements of humanized milk (cold weather)

Weight of infant, lbs.	Total amount in 24 hours, oz.	Number of feeds in 24 hours
10	25	6
11	27½	6
12	30	6
13	32	6
14	34	6
15	36	5
16	38	5
17	40	5

Precautions.—1. It will be noted that no figures are given in the above table for very small infants. *The mixture is likely to be too rich in fat for very young babies* and recourse must be had either to a more dilute diet or the mixture must be predigested.

2. The method is quite unsuitable for the hot weather.

3. Artificial feeding should never start with full strength humanized milk, it is difficult for the infant to digest fat in whatever form in the same quantity and proportions as in human milk. The milk should be gradually strengthened as the child shows tolerance.

Alternative method of preparing humanized milk—top-milk method.—The term top-milk is applied to the upper layers of milk which has stood for some time and into which the main cream content has risen. Top-milk, by suitable dilution, can be converted into a food of balance closely approximating that of breast milk. One pint or one quart of fresh milk is placed in a glass douche can, surrounded by ice, or, if preferred, a convenient apparatus, Maw's milk humanizer, may be obtained.

The amount of cream which will rise to the upper layers will depend on the length of time of standing.

Taking a good average milk with fat percentage of 3.4 to 3.8, after four hours the composition of the top quarter will be:—Fat, 7 per cent; protein, 4 per cent; sugar, 4 per cent. The top quarter only is used, the lower three-quarters being syphoned off. This is diluted to half, with the resultant composition of protein, 2 per cent; fat, 3.5 per cent; and sugar, 2 per cent.

Sugar at the rate of 1 ounce to one pint of the mixture is finally added.

The resulting mixture may thus be compared to human milk:—

	Protein	Fat	Sugar
The mixture ..	2 per cent	3.5 per cent	7 per cent
Human milk ..	1.5 "	3.9 to 4 "	7 "

It is essential that the milk be stood on ice or kept in a refrigerator during separation.

The slightly lower fat content and higher protein content of the top-milk mixture are to be regarded as desirable.

POINTS COMMON TO ALL METHODS

The addition of sugar.—For the young infant, milk sugar which may be obtained from any chemist is desirable; it is identical with the sugar of human milk and is less likely to give rise to fermentative dyspepsia. With the increasing demands of older infants the amount of sugar required to maintain the balance amounts to two ounces. Many infants will not tolerate so large a quantity, which gives rise to intestinal fermentation, but half may with advantage be replaced by dextri-maltose, such as Mellin's food.

Addition of other factors.—Lecithin powder, grain 1, daily, in one bottle until such time as the child is old enough to take egg-yolk should be added (Pritchard).

Vitamin content.—As the sterilization of milk will have an adverse effect on the vitamin content, we should guard against any possible deficiency. Cod-liver oil contains an ample supply of vitamins A and D and may be administered in the form of an emulsion daily.

To replace the anti-scorbutic vitamin, orange juice, grape or tomato juice two to four teaspoonfuls daily may be given.

Vegetable soup.—The accessory food factors are required in minute quantities only, but are nevertheless essential to perfect nutrition. In order to ensure that there is no shortage of extractives or mineral salts in absorbable form, a soup made from vegetables and bone may with advantage be added to the diet, even as early as the fifth month. Such an addition will be found of particular value at the time of the appearance of the first teeth.

The following figures will be found of use:

1. The increase by five ounces of milk to a pint of the humanized mixture raises the protein content by 1 per cent, *e.g.*,

Milk 10 oz., water 10 oz.			
Composition: Protein,	Fat	Carbohydrate	
1.75	2	2.25	
Milk 15 oz., water 5 oz.			
2.75	3	3.4	

2. Every ounce of 33 per cent cream added to one pint of milk mixture raises the fat content by 1.5 per cent.

3. Every ounce of sugar added to the mixture raises the percentage by 5 per cent.

The second method of calculation is by the calorimetric method. When modifications are required to suit individuals, the method will be found a reliable guide.

At the same time, figures based on calculations cannot be taken as rigid. Just as in the quality of food, so in the quantity, allowance must be made for individuality. Requirements will depend to a large extent on the uses to which the food is put. Some will be burnt up to produce heat, so that the child will require only two-thirds or three-fourths of the cold weather allowance when it is hot. Want of attention to this point is responsible for many cases of digestive disturbance on the voyage out to India and on transfer from the hills to the plains.

The food value may be expended as energy, a vigorous kicking baby will require more than a lethargic one. The first experiments in sitting, walking and standing will make especial demands on the energy.

The food value may be expended in growth more rapid than normal. A small rapidly-growing baby will require more proportionately than a larger more slowly-growing one, and an infant building up after a wasting disease may require as much as 25 per cent above the average requirements for its age and weight.

The average size of the child's stomach is as follows:—

(Pritchard)

Age	At birth	Weeks				Months	
		2	4	8	12	5 to 6	10 to 11
Weight in lbs.	7	7½	8	9	10	13 to 14	18 to 21
Capacity in ounces.	1 to 2	1.5	2	3.37	4.5	5.75	8.14

The stomach is, however, to a certain extent an adaptable organ and the actual size will depend, within limits, on the usual size of the feeds. The normal stomach will easily accommodate one-sixth of the total requirements of food in the 24 hours, except in very young children.

In the maze of instructions and calculations, the real test of successful feeding must not be missed. The aim is to produce a happy healthy baby with a good digestion and showing a steady rate of progress. The successful feeding consists, not only in administering food suitable in quality, quantity and cleanliness, but a careful appreciation of the results and, if necessary, a judicious modification to suit the individual requirements.

The feeding tables are laid down for the average healthy baby, but it is impossible to provide one form of diet suitable for all babies.

Modifications will be necessary to suit the individual, and the diet must be made to agree with the child and not the child with the diet.

TIMING THE FEEDING

The question of the frequency of feeding is a matter which has excited much attention of recent years and there seems little reason to doubt that, with the introduction of more modern methods with longer intervals, there has been an improvement in the health of naturally and artificially fed infants. Above all *regularity is essential*, the child becomes trained to expect the meal at definite times and the stomach is fully emptied between each meal. The practice of feeding the child whenever he cries can only lead to ill health. *Night feeds are not necessary* unless the habit is contracted in early life, they disturb the rest of both mother and baby. The majority of babies thrive well on four-hourly feeds from the first, that is five meals a day; though there are some who require more frequent feeding in the earlier months.

The choice of the diluent to milk.—There are three substances commonly added to milk with a view to preventing the formation of a heavy curd in the stomach, which is such a serious obstacle to digestion.

Lime water.—One teaspoonful or so to each feed does undoubtedly prevent the formation of curd, but unfortunately causes constipation, and may, after prolonged use, set up intestinal irritation. The administration of lime water with a view to promoting bone formation is unnecessary and probably useless.

Sodium citrate added to milk in the proportion of two grains to each ounce of milk is of great service in tiding a delicate child over a period of indigestion, but it is not to be recommended as a permanent constituent of the diet. The action of sodium citrate is to inhibit the gastric digestion by neutralizing the hydrochloric acid of the gastric juice. Digestion is either postponed till the food has passed the stomach or the intestinal juices are enabled to regurgitate and act in the artificially alkaline medium in the stomach. This will reproduce one of four effects: (1) The acid barrier, always weak in infants, will be broken down and the way laid open to invading microbes. (2) The production of acid may be overstimulated and so the habit of overproduction, and acid dyspepsia, established. (3) The stomach misses the educational exercise of early infancy. (4) The initial stimulus to digestion throughout the alimentary canal is lost. Further, in certain susceptible children the administration of citrate gives rise to oedema.

Barley water acts mechanically and prevents the formation of a dense clot. At the same time, the introduction of unaltered starchy food into the dietary at this period is not altogether

desirable and the cereal action, to be discussed later, must not be overlooked.

Taken in all, the best diluent is boiled water. If the water be first boiled, and while still hot, the milk be added and well stirred, the heavy clots will not form.

Sterilization.—Owing to the changes and chances to which milk is subject, the occasions on which it is possible to advise the giving of raw milk are rare. Generally speaking, it is desirable to undertake some process of sterilization. Strictly speaking sterilization implies the destruction of all germs and the rendering of milk absolutely free from all living organisms. In practice this is not feasible, as some organisms, the spore-bearing groups, are so resistant that the amount of heat required to kill them would so materially alter the character of the milk as to render it unfit for consumption. The majority of disease-bearing organisms are, however, killed at lower temperatures. If milk therefore be raised to the temperature of boiling water, 212° Fahrenheit, and kept at that temperature for three minutes, it will be rendered free from the common disease-bearing germs. The milk will not have been boiled, as milk boils at a higher temperature than water, so there will be little alteration in taste. How far the process affects the vitamins is uncertain, but it is well to regard them as at a low level and to ensure their presence by the daily administration of cod-liver oil and orange juice. Apart from this, there is no evidence that the nutritional value of milk, subjected to this treatment, has been impaired.

For convenience and efficiency some form of the Soxhlet sterilizer is recommended. The apparatus consists essentially of a series of bottles, each to hold one feed for sterilization, a rack to hold them and a vessel in which the bottles are heated.

The advantages are that the milk mixture for half or the whole day can be prepared at one time, separated into feeds of appropriate size and sterilized at one time. On cooling, the bottles are automatically sealed. There is thus a considerable saving of time and the risk of contamination is reduced to a minimum.

For use, the food supply for half or the whole day is calculated, divided into the number of feeds, and each feed is put into a separate bottle. The water in the boiler is brought up to boiling point and kept there for three or four minutes. The bottles are then removed and cooled as quickly as possible and then stored on ice.

When a feed is required, it is warmed to 100°F., the rubber cap removed and replaced by a nipple.

THE FEEDING OF INFANTS ON DRIED OR CONDENSED MILK

The indications for the use of some form of preserved milk are broadly—

1. When the milk supply does not come up to the necessary high standard for infant feeding.

2. When the infant is placed on artificial feeding at a time when there is reason to expect that the necessity for further change will arise in the near future.

3. In times of epidemics.

4. Certain delicate infants, unable to digest fresh cow's milk, however modified, may be found to thrive on some form of milk powder.

In the matter of the potentialities of preserved milks the following extract from the well-known textbook *The Physiological Feeding of Infants and Children* by Dr. Eric Pritchard will be found reassuring:

'If a group of independent observers would take a series of infants and would feed them on dried milk modified to breast standard and would comply with all other physiological conditions, I am perfectly certain that they would come to the same general conclusion that I have come to after fifteen years' experience in the management of nearly 3,000 infants fed exclusively on dried milk, namely, that if this method does not give as good results as any other method, it is not the fault of the milk, but of the manner in which it is used'.

DRIED MILKS

The advantages of dried milks are:—

1. They are of known and uniform consistency.

2. They are easy to manage in the hot weather. If preferred, each meal may be prepared separately and there is no danger of it going sour.

3. The food is, as a rule, easily digested, more easily digested than fresh cow's milk, as the curd formed is much finer. Two preparations of pure milk, with a modicum of added carbohydrate, are commonly available in India. These are Sunshine Glaxo, and Cow and Gate. A study of the table reveals that the fat and carbohydrate content is approximately suitable to the Indian climate, but that the protein figure is that of cow's milk and therefore high for infant feeding in the early months. By using these foods, however, in the proportion of two measures to three ounces of water, we obtain a more suitable protein figure in a mixture of which the contents are as follows:—

Protein, 2 per cent; fat, 1.6 per cent; carbohydrate, 3.9 per cent.

It is therefore desirable, having made this dilution, to add carbohydrate in the form of milk sugar or dextri-maltose (e.g., Mellin's food) in the proportion of one heaped teaspoonful to five ounces. We may then give this mixture at the rate of 2½ ounces per pound body weight in the 24 hours. If the baby does not thrive or is constipated, we may add cautiously some form of cream (see below) as the fat content is somewhat low.

In using dried milks, we must not fail to consider the vitamin content. It is now held that, in dried milks, the vitamins A and B are present in sufficient quantities and that the vitamin C is absent. At the same time, making an exception of those foods to which vitamins have been specially added, it is well to safeguard against any shortage by adding a small quantity of cod-liver oil and fruit juice. In the hot weather, however, cod-liver oil is likely to give rise to indigestion and one of the concentrated preparations, such as Ostelin (vitamin D), Radiostoleum (vitamins A and D), or Adexolin (vitamins A and D), must be used.

Sometimes, in spite of the utmost care a regime such as the above does not suit the infant. In such cases, if there is evidence of protein indigestion, we may try Allenbury's No. 1 which is particularly suitable for delicate infants. Other infants flourish on acidified milk (see below).

It cannot be too strongly emphasized that the selection of a food should be based on a full knowledge of the contents and the requirements of the individual and that a change should not be made without reason and without plan in selecting the substitute. The trial of one food after another, with no knowledge of the contents and no appreciation of the requirements of the infant, is unfortunately a common practice.

Condensed milks are not to be recommended as a routine, the sweetened form contains a sugar content far in excess of requirements, and the unsweetened form has a high protein and low fat content. At the same time such milks have their value in times of trouble.

Suitably diluted, they may be found valuable in the case of a wasting baby, but the sugar content is excessively high; vitamins are deficient or absent, and prolonged use will lead to the development of rickets.

Ideal milk diluted 1 to 8 is half and half cow's milk and water. As the basis of a mixture it may be useful, as the fat appears to be more easily digested than that of dried milk.

The composition of the more commonly used prepared milk foods with low fat and carbohydrate, but high protein content, are given below :—

SUNSHINE GLAXO (diluted 1 to 8)—

Fat, 2.5; protein, 3.1; carbohydrate, 5.8.

Iron, 5 parts per 1,000,000.

Vitamin D, 130 I.U. per pint.

Caloric value, 135 per ounce of powder.

The average child in the hot weather will therefore require just over two measures of the powder for each pound of the body weight, in 24 hours. Fruit juice only need be added, but fruit juice should be taken.

COW AND GATE (diluted 1 to 8)—

Fat, 2.3; protein, 3.37; carbohydrate, 5.7.

Caloric value, 135 per ounce of powder.

Average requirements for child as for Sunshine Glaxo. Vitamins, e.g., Ostelin and orange juice, should be added to the diet.

Foods containing low protein and high carbohydrate. Suitable for delicate children and those suffering from protein indigestion as a temporary feed :—

Allenbury's—

No.	Albumin	Casein	Fat	Lactose	Dextri-maltose	Caloric value
1	0.7	1.0	3.1	7.3	3.25	134
	1.7			10.55		
2	0.7	1.15	2.9	6.7	3.8	134
	1.9			10.5		

Irradiated ergosterol should be added.

HORLICK'S MALTED MILK POWDER—

Protein, 13.8; fat, 9; carbohydrate, 70.8.

MELLIN'S FOOD—

Pure dextri-maltose.

A good cream supply is more difficult to obtain than a good milk supply, the fat value of the cream is inconstant and often unknown. Yet there are times when it is desirable to increase the fat content of the food, especially if we are using diluted milk.

A great deal of research has been devoted to the preparation of an artificial cream which will present not only all the essential characters of natural cream, but some advance in the matter of digestibility. Such creams are prepared from animal and vegetable oils reduced to a fine degree of emulsification, so that the fat is presented in the form of minute droplets easily attacked by the digestive juices. Some of these creams are designed not only to supplement the fat content but also to ensure against any deficiency in the milk or milk powder to which they are added. For this purpose, fresh butter from cow's milk, or cod-liver oil form a proportion of the ingredients, as both are rich in fat-solubles A and D. Such creams must not be expected to replace any deficiency of vitamin C, for which fresh fruit juice must be given. The advantages of such creams are manifest, and they may be used in conjunction either with fresh or dried milks.

One of the great difficulties of artificial feeding of infants is to keep the fat content at an adequately high level, as the infant is apt to be intolerant of fat from other sources in the same proportion as in breast milk. An artificial cream, with the type of fats well balanced and the fat globules finely divided, has been found in practice to be more easily digested than fresh cream. Further, it is of known and uniform strength, sterile and always available. Examples of such creams are New Zealand cream prepared after the formula of Sir Truby King, and Brestol. They must be used with caution in this country, but are valuable additions to the diet in the cold weather and, further, are well taken by children as a substitute for butter.

A further method of increasing to a small degree the fat content and making up any deficiency in vitamins, is to add to the bottle a cod-liver oil emulsion such as that of the Great Ormond Street Hospital, given below:—

R Cod-liver oil	η 30
Mucilage of acacia	η 5
Almond oil	η 1/16
Oil of cinnamon	η 1/40
Elixir of saccharin	η 5
Chloroform	η 1/16
Benzoic acid	grs. 1/16
Decoction of Irish Moss	to 1 drachm.		

One teaspoonful two or three times a day in the feed.

ADDITIONAL FACTORS

At least two teaspoonfuls of fruit juice daily should be added to all feeds, and lecithin and broth may be given, as for cow's milk feeding.

SPECIAL METHODS OF FEEDING

Predigestion of milk or milk mixtures.—Predigestion will be found of great value not only to delicate infants but also in the feeding of older children during the acute stage of illness. In order that the full benefit may be obtained, the ferments must be given ample time to act, the common method of allowing ten minutes or a quarter of an hour is of very slight value.

After a period of feeding on predigested food, it is desirable to allow the digestion of the patient to assume its functions gradually; for this purpose the time of predigestion should be shortened by stages.

Method.—Take one pint of milk or milk mixture prepared to the correct formula, bring quickly to the boil and cool down to about 117°F. Add two teaspoonfuls of liquor pancreaticus (Benger) or other suitable digestive powder. The temperature of the mixture is maintained at about 117°F. by placing the vessel in a container of water at 120°F. Stir occasionally.

The digestion is allowed to proceed for from one to three hours, at the end of which time the mixture is brought rapidly to the boil and cooled in the ice-chest.

Modification to suit the individual may be made by skimming the milk before digesting and adding lactic acid, 2 drops to each ounce, before administration. Sugar or dextri-maltose may be added to suit the case.

Fresh butter milk or skimmed milk.—This is a form of food to which frequent recourse will be had during the hot weather, when the full fat content of milk may cause digestive disturbance; it is also of value in fevers, when full-cream milk is distasteful and unsuitable and it is used for those infants who show evidence of weak fat digestion. It may be prepared on the same principle as top-milk, using the lower three-quarters instead of the

top quarter. The percentage composition is approximately:—

Protein, 3 per cent; sugar, 4.8 per cent; fat, 0.5 per cent; caloric value, 10 per ounce.

Butter milk (Glaxo).—A new preparation known as butter milk powder G. L. formula has proved of value in a number of cases showing high intolerance to fat. It may be used diluted one in ten when the formula is as follows, or somewhat stronger.

Reconstituted

	Per cent
Fat	0.55
Protein	3.35
Lactose	4.2
Ash	0.75
Lactic acid, citrates, etc.	0.15
Caloric value, 10.2 per ounce.	

Artificially acidified milk.—The physiological reasons on which this form of feeding is based are that the normal hydrochloric acid content of the gastric juice of infants is low, is easily abolished in illness or conditions of exhaustion, and that the mineral salt content of cow's milk is proportionately so high that the available acid is fixed and none is left for digestive purposes.

The consequence is that not only is the gastric digestion incomplete or inert, but that the stimulus to digestion power in the alimentary tract is wanting.

The writer has found this method invaluable in that state of exhaustion following a prolonged digestive disturbance, when it is difficult to stimulate the digestion to any signs of activity and also for those babies who may be termed difficult feeders, who are slow to develop to normal digestive capacity and refuse to thrive on any modification of cow's milk.

The acid added may be either organic or inorganic, lactic acid or hydrochloric.

Preparation.—The preparation of lactic acid milk is as follows:—

One pint of milk is boiled, cooled and the skin removed. To this is added 45 minims of lactic acid (British Pharmacopœia) drop by drop, stirring four times between each drop.

The milk must not be heated after the addition of the acid or it will curdle.

This method may be used also with milk prepared from a dry milk powder.

Dilute hydrochloric acid 2 to 4 minims to each feed may be used with advantage in conjunction with predigested milk.

Lacidac (Cow & Gate Co.) is a dried milk with the necessary quantity of acid already added. It is used in the same way as the ordinary dried milks and is easy to prepare.

CALORIMETRIC METHODS OF ESTIMATING THE FOOD REQUIREMENTS OF INFANTS

The caloric value of human milk is 20 per ounce and from the amounts of milk taken by average healthy babies that we are able to fix

the caloric requirements of infants. Thus a child of 10 pounds weight requires 35 to 50 calories to each pound of body weight and a child of 20 pounds 30 to 45 according to the climate.

This method of calculation is of great value in the feeding of those infants whose digestion demand a divergence from routine lines. For instance, a child shows signs of intolerance of fat, and the fat of the diet must be reduced. By the calorimetric method, it is easy to estimate the amount of reduction and replace the deficit by other food of equivalent caloric value. It is not wise to apply the method too closely in the case of delicate infants, but, at the same time, a careful count of the caloric value should be taken daily, so that should the child, of necessity, be underfed, the fact does not escape notice and early efforts may be made to bring the diet up to the required standard.

Example.—It is decided to feed a child, who is convalescent from a digestive disturbance, on milk and water half and half.

The child is 10 pounds in weight and should normally take 25 ounces in the course of the day.

Twenty-five ounces of the above mixture at 10 calories per ounce is 250 calories.

A child of 10 pounds weight requires 350 (i.e., 10×35) calories. The child is, therefore, though receiving the correct bulk of fluid, underfed. The fact is appreciated and as the digestion settles, efforts are made to make up the deficit. Each ounce of milk added to the mixture raises the value by 18 calories, the addition of one teaspoonful of sugar or malted starch by about 14.5 and one teaspoonful of medium cream by about 10.

Cautions and exceptions.—The chart should be used not only with reference to the weight, but also to the age of the baby. Infants below the average weight will require more proportionately even up to 70 to 75 calories per lb. Conversely, fat children above the average weight will require less per pound.

Calorific calculation is not admissible till the child is established on a diet. At the commencement of weaning or in the first few weeks of life, the child must be underfed in terms of calories. Similarly, when it is found, for any reason, necessary to change the type of feeding the full caloric requirements must be approached gradually.

After the ninth month, there is a period of gradual advance from the purely infant diet to that of childhood. This is not a matter merely of additions, but also of replacements. It will be necessary to make reductions in certain items of the diet, notably milk, butter may take the place of cream and bread of baked wheat or sugar. It is necessary to know the food value of each article added and the total caloric value of those to be replaced. The fruit juices which change can be satisfactorily

WEANING AND DIET IN CHILDHOOD

General principles.—Every article legitimately considered as food may be said to consist of two parts, one which can be so altered by the digestive juices of the body as to become available for absorption into the body, and the other, known as the roughage, more or less untouched by digestion, but having its uses in stimulating the bowel and serving as a medium to carry away substances formed during the elaborate chemical processes of the body, which, if retained, would act as poisons. In the infant, some proportion of the fat in the food serves this purpose. The digestible portion of the food consists firstly of three main groups of chemical bodies, each group having different chemical formation and different function, though the functions are to a certain extent interchangeable. Each common article of diet contains one or more of these fundamental groups in varying proportions thus :

	Protein	Carbo- hydrate	Fat
Cow's milk	3.5	4.5	4
White bread	7.2	41.8	0.2
Egg, white	10.7	0.0	0.1
Egg, yolk	15.5	0.0	33.3

Each constituent is essential in due proportion and its deficiency cannot be made up by excess

of others, so that the rate of growth and progress is limited by deficiency in one constituent however plentiful the others may be. It is therefore important that the sum of the primary elements be in due proportion and amount to the needs of the body at any particular age and varied to some degree in accordance with occupation.

PROTEINS

Proteins available as food supply are widely distributed throughout edible materials. During the process of digestion proteins are split up into less complex bodies, the amino-acids, which are subsequently reconstructed in the tissues to form living proteins, and to carry out the main functions of growth and repair of tissues and elaboration of secretions. The food proteins are not all of the same structure; the amino-acids derived from them differ and are not all equally valuable in the reconstruction of a particular form of protein suitable to the individual. We therefore describe those proteins which afford the highest quality of suitable amino-acids as proteins of the first class. These proteins are mainly found in animal food and the source of supply in early life is from milk. The value of milk as an additional food factor during later childhood has been proved. Proteins may also be converted into energy, but this is an extravagant and undesirable process as poisonous waste products are formed which will throw an extra strain on the liver and kidneys. It is desirable that a protein balance be established (*see below*) the body taking in the full amount of protein required but no great excess. In the child the amount is two grammes per kilo body weight or approximately 30 grains to one pound, diminishing as age advances and the rate of growth abates.

Suitable proteins.—These are milk, curds, cheese, eggs, kidney, liver, meat, sweetbreads, fish, green leafy vegetables such as spinach, lettuce and young solo carrots, and whole wheat flour to some extent (McCarrison).

FATS

The deposit of fat in the body serves to keep the organs in place, to protect the more delicate structures from injury and as a heat regulator. Fats used in the body chemistry are a source of heat and energy and are necessary for the provision of certain more obscure chemical bodies essential to function. They are also an important item of the food as a source of vitamins. Fat storage in the body is most easily and directly obtained from fat in the food though it may be formed from other food constituents, particularly carbohydrate.

CARBOHYDRATES

This group includes sugars and starches of all kinds. A source of heat and energy, they are easily burnt up to simple innocuous bodies throwing no strain on the excretory organs. In order to render the combustion of fats complete,

the presence of carbohydrates in a proportion of at least 1.5 carbohydrates to 1 of fats is necessary.

The amount of carbohydrates in the food is usually adequate but if there is an excess of fat in the food the carbohydrates may prove insufficient for the complete combustion and the child is liable to develop acidosis. Further, children of a particular type, the nervous, highly strung and energetic type, are liable to utilize available carbohydrates quickly and the supply therefore must be large and given at frequent intervals lest symptoms of exhaustion supervene. The blood sugar of a child is subject to a considerable variation and the amount is rapidly reduced when the period of abstinence from food is prolonged. It is therefore advisable that the child should not go for more than four hours without food and that after any period of forced abstinence the first food taken should be of carbohydrates.

A well-balanced diet is an acceptable palatable diet, which, on analysis, is found to contain the different essential constituents in just such proportions as they are required by the individual.

A consideration of these functions will lead to the just deduction that, having regard to the varying activities of the human race, one standard of diet will not do for all, the infant is engaged in growing, at an enormous proportionate rate, while the adult, having ceased to grow, requires nutriment for repair and the production of energy, and so the balance cannot be the same.

It has been estimated that for the infant the correct balance of protein to non-protein is 1 to 7, altering slowly with advancing age till for the adult it is 1 to 6 or 5.5.

The fat proportion differs even more markedly.

	Fat	Carbohydrate
Infant ..	1	2
Second year ..	1	3.3
Adult ..	1	10

These proportions are frequently neglected, particularly in regard to the diet of young children, whose diet includes such a large proportion of cow's milk that the protein-non-protein ratio is often 1 to 3.

MINERAL SALTS

In addition to the prime principles, there are other constituents minute in quantities, but no less essential to health and growth. Mineral salts are required, not only for bone building, but they play an essential part in all the complicated chemical processes of the body in life. A deficiency of one or other may cause striking effects, a want of iron will cause anæmia, a deficiency of calcium may lead to convulsions, and a deficiency of iodine may bring in its train a series of severe symptoms.

In India, particularly in Bengal, or other countries on an alluvial soil, there is consider-

able difficulty in maintaining an adequate mineral supply owing to the poor mineral content of the vegetables which are the main source of supply. The vegetable broth is a convenient vehicle for maintaining the supply for young children. There is ample evidence that mineral deficiency, especially calcium and iron deficiency, is extremely common and it is therefore necessary periodically to supplement deficiency by the administration of these minerals in the form of tonics. The deficiency may be made up but the retention and utilization of the minerals can only take place where there is also an adequate supply of vitamins. The prevalence of nutritional anæmia in Bengal is due to the want of these accessory food factors.

List of foods affording good supply of mineral salts :—

Calcium (lime)—milk, butter milk, cheese, whey, yolk of egg, dāls, fruits of all kinds and green leaf vegetables.

Phosphorus—milk, butter milk, eggs, dāls, wheat, oats, barley, spinach, carrot, cauliflower, brussels sprouts, meat and fish.

Iron—liver, red meat, eggs, dāls, whole cereal grains, spinach, leeks, lettuce, onions, tomatoes (R. McCarrison).

VITAMINS

These bodies are known by the effect of their presence or absence. They may be considered as the spark that ignites the food fuel. Of late years, a substance considered identical with vitamin D has been produced by the action of ultra-violet rays on cod-liver and other ergosterol-containing oils, but beyond this we know them by their habitat, their virtues and the means by which they may be destroyed. One fact we are sure of, that these vitamins, intangible though they may be, are essential to health and we associate a definite train of symptoms with the absence or deficiency of one or other of the groups into which they are divided.

Medical men are familiar with diseases which develop in the absence or gross deficiency of one or the other of the vitamins, such diseases as rickets and scurvy, but, as Sir Robert McCarrison has pointed out, the deviations from health as a result of minor deficiencies are not fully appreciated and it is in infant and child feeding as a whole that we must guard against the minor deficiencies.

At present five main divisions are made, but of recent years there have been further subdivisions according to the properties ascribed to them as the result of experiments carried out with diets in which different fractions of the vitamins were absent or deficient. It is not necessary at this juncture to enter into a minute classification. It will be more appropriate to consider the properties and results of deficiency of vitamins under the main groups.

PROPERTIES OF VITAMINS

Fat-soluble vitamin A. Growth promoting, provides resistance to infection, deficiency produces xerophthalmia. Chief sources :—fresh milk, butter, cream, cod-liver and halibut liver oil.

Water-soluble vitamin B. Growth promoting. Complete absence will produce beriberi. If the supply is insufficient the results will be loss of appetite, indigestion and general irregularity in the function of the alimentary canal. There will be loss of weight, and general weakness with lack of vigour and a tendency to anæmia. Chief sources :—whole meal, whole grain, vegetables, yeast.

Water-soluble vitamin C. Anti-scorbutic. Chief sources :—fresh vegetables and fruits.

Fat-soluble vitamin D. Controls the phosphorus and calcium metabolism of the body. Prevents rickets and diseases associated with calcium deficiency. Chief sources :—articles containing vitamin A, and sunlight.

Vitamin E. The reproductive (of importance in later life).

Although these distinctions are made, there is ample evidence that the vitamins are to a certain extent interactive and that the general well-being of the child depends on an adequate supply of all varieties. These bodies, so essential to health, are unfortunately delicate. By prolonged cooking during the process of preservation of food and in tinned foods much of the vitamin value is lost.

It has been emphasized elsewhere that the vitamin content of the mother's diet must be adequate, if the baby is to be born healthy and if she is to feed it satisfactorily.

WATER

The human being can live for many days on water only, a fact which has not only been proved by the historic feats of professional fasters, but is a matter for daily observation when dealing with the sick. The converse does not hold good, and particularly in infancy, does the deprivation of water or excessive loss of fluid produce early menace to life. There is a constant exchange of water in the system, it is a component of all living tissues, it supplies the necessary fluidity of the blood and it dissolves and carries away waste products from the body.

The child, in proportion to its size, requires more water than the adult. The requirements of the average infant are calculated at 2½ ounces or more for each pound of weight. It is a cruel and hurtful thing to deny the free use of water to children. The error of taking too much is not likely to be committed. Some children, indeed, do acquire the habit of drinking water more frequently than is necessary and they require guidance. A child should be discouraged from taking large draughts at the beginning of

a meal though a draught taken an hour or half an hour before does no harm.

It is to be remembered that in hot dry climates, both through respiration and perspiration, the amount of fluid lost from the body is vastly increased and that this loss must be replaced.

In illness, particularly in diarrhoea, when the loss of water from the body reduces the available fluid to dangerously low levels, the first aim and the essential treatment is to replace this fluid by some means or other before the serious symptoms of water deprivation show themselves.

DIET AFTER THE APPEARANCE OF THE FIRST TEETH

Although it is customary to regard the age of nine months as that at which the diet of the infant should be changed, or rather, other forms of nourishment included in the dietary, it may be laid down as an axiom that the change should be made, not rigidly according to age, but according to the maturity of the system as indicated by the appearance of the teeth. In the case of a backward or delicate child we should naturally incline to delay and allow the child to have the benefit of the easily digested breast milk for some weeks longer. On the other hand, exceptionally vigorous and advanced infants may demand more concentrated food at an earlier age than is usual. Till the appearance of the first teeth, however, no change is made. Before this, the digestive functions have not matured sufficiently to deal with diet other than breast milk or its artificial equivalent. At the same time, though the appearance of the first teeth is the signal for advance, no change should be made during the actual eruption, a time when the digestive system is particularly sensitive to strain.

The secret of success in the transition to mixed diet lies in the gradual education of the digestive system and the consolidation of each step before a further advance is made. The commonest errors made are :—

(1) The first additions are made too suddenly. The bottle feeds are thickened to a degree incompatible with digestion.

(2) No provision is made for the development of the jaws by the supply of solid food, baked crusts or rusks. This should be the first addition as soon as there is any sign of the onset of dentition.

(3) The maintenance in the later stages of too large a quantity of milk in the diet, so that the child has no appetite for other forms of food and the balance is incorrect.

(4) The addition of more than one new article at a time, so that, in the event of disagreement, it is difficult to know the precise article on which blame should be laid.

(5) Insufficient attention to the vitamin content.

WEANING

The first step is the change from the breast to the bottle. Amongst European mothers, it is usual to accustom the baby to artificial feeding before proceeding to mixed feeding. This is not essential, but, in the interests of the mother, she may be considered to have done all that she safely can, if she has fed the baby till the arrival of the first teeth. Considerable practical difficulties in nursing arise when the teeth are in the process of eruption and the baby is biting hard at anything which is placed within the mouth.

The process of weaning should be gradual, one meal at a time being changed, the whole process being accomplished in from three to five weeks. For this reason, weaning may be commenced towards the end of the eighth month, so that the baby is ready to make further advances as the system demands. There is still the same necessity for maintaining the physiological balance, so the substitute may, with advantage, take the form of humanized milk, though at first the fat content should be kept at a definitely lower standard than that of breast milk. The balance is at this time gradually altering, with an increased demand for carbohydrate (farinaceous) food. At two years the proportion of carbohydrate to fat is 3.3 to 1 instead of 2 to 1 as in infancy. The proportion of protein in the diet is also very slightly raised.

During the process of weaning the child will, if fed on humanized milk, have become accustomed to some form of malted starch, so that the next step may be in the form of an unchanged carbohydrate; rusks, groats, baked flour or oatmeal jelly, such food being added in a tentative manner and the result observed. Of all these articles, the first to be added will be the rusk or baked crust, which will teach the child to chew, develop the jaws and assist in the cutting of the teeth. If, on the contrary, the baby has been accustomed to whole milk feeding, or some approximate dilution, the first step will be to add some intermediate food, such as Mellin's, to the diet and then proceed to the introduction of the unaltered farinaceous food.

MIXED DIET

Though considerable advances will be made within the next three months, milk will be the basis of the diet, and if the child has been fed on humanized milk mixture, the milk content in this will be gradually increased, while the added cream will be correspondingly diminished, till at the end of the year the child is taking pure cow's milk.

At the same time, with the addition of the farinaceous food to the bottle, the sugar will gradually be reduced.

The number of meals in the day is reduced by the gradual cutting down of the ten o'clock

feed, till ultimately the meals are four in the day with the addition of an early morning drink of fruit juice, sugar and water. This must, of course, be subject to circumstance; when the children take their airing in the early morning, something more substantial must be given. As to timing, in India, the time-table for the child is fixed according to atmospheric conditions and the most suitable hours for outdoor air and exercise.

The tenth month of life, therefore, is spent in weaning, the only addition being at first rusks, one given a quarter of an hour before two or three meals. Later, a small amount of baked flour, groats or oatmeal jelly may be added.

If vegetable broth has not been given at an earlier age, it should now be introduced, from four to five ounces being used as a substitute for water in one of the bottles.

The amount of milk or milk mixture at this age will be from thirty-eight to forty ounces in the day.

Age : 10 months, 11th month of life.

Additions : Groats or baked flour; milk pudding, made from rice or sago, starting with two teaspoonfuls; egg yolk on alternate days, starting with one teaspoonful; gravy and beef tea.

The total amount of milk, 30 to 35 oz.

Water will be necessary between meals.

Age : 11 months, 12th month of life.

Additions : Gravy and potato; egg or steamed custard; bread and butter.

Total amount of milk, 25 to 30 oz.

The diet from the 13th to the 18th month :—

Early morning: Orange juice, sugar and water.

Breakfast: Toast and butter, one slice; barley jelly or strained oatmeal; milk, 8 oz.

Lunch: Gravy and potatoes or boiled egg and breadcrumbs; milk pudding; bread, one small slice or rusk or toast; vegetable soup; milk, 4 oz. in pudding, or stewed fruit.

Tea: Milk, 8 oz., rusk; bread and butter; sponge cake.

Cocoatina may be added to the milk.

The milk may now be given pure or, in the hot weather, with one-quarter of its bulk in water added.

After the fifteenth month, steamed fish or brains or pounded chicken beginning with one tablespoonful may be added.

Age : 18 months to 2 years.

Early morning: Fruit juice with sugar and water.

Breakfast: Groats or strained oatmeal with milk, treacle or sugar; milk, 8 oz.

Lunch: Fish or pounded chicken or brain, or chicken pish-pash; once or twice a week, liver and spinach soup; stewed green vegetables, young carrots or vegetable soup; milk pudding or stewed fruit or junket; water to drink.

Tea: Rusks, biscuits, sponge cake; honey or fruit jelly; milk, 8 oz.

Supper: Cup of milk with biscuit of Horlick's malted milk.

Note.—Total milk, including that used in cooking, 1 to 1½ pints. A boiled cutlet or other suitable bone should be given daily for a few minutes for the child to gnaw.

Age : 2 to 5 years.

Early morning: Orange juice or grapefruit juice or tomato juice with sugar to taste.

Breakfast: Porridge or groats with milk, sugar or treacle; eggs three days a week; bread and butter or crisp toast with honey or fruit jelly; milk, 8 oz.

Lunch: Fish or meat (mutton, beef or chicken); potato, baked, mashed or boiled; mashed vegetables (cauliflower, carrots or greens); milk pudding with stewed fruits, junket or custard; water to drink.

Tea: Toast and butter; sponge cake; honey or fruit jelly or stewed fruit and custard or junket; milk 6 to 8 oz.

Supper: Cup of milk or Horlick's malted milk.

Note.—Total amount of milk 16 to 20 oz.

The following vegetables are suitable for young children:—Peas, vegetable marrow, boiled cucumber, Jerusalem artichokes, cauliflower, young cabbage or carrots well mashed, onions. Before 18 months, they are best given in the form of strained vegetable broth.

GENERAL PRINCIPLES

The advance to mixed feeding is one of education, each step must be taken cautiously with due observation of the results. It must be borne in mind that if the child is upset by the too rapid addition of new forms of food, his progress may be delayed for months.

Above all, the child must be instructed in that most important preliminary to digestion, the proper mastication of food. Without this, the teeth cannot be properly cut, the jaw will not develop, and the shape of the face will remain immature. Further, there will not be due expansion of the nasal airway, so that any tendency to adenoids may be perpetuated.

Rest after a meal, for a short time, is always desirable, as all the nervous force is required for digestion.

Salt should be added in moderation to all meals, but children should not be allowed to partake immoderately, as many will if permitted.

Eating between meals must never be permitted though water may be allowed and should always be available.

Sugar is perfectly harmless in moderation, but in excess it causes acidity and fermentation, and perverts the appetite. A moderate amount of ripe fruit may always be given with safety to a child over two years of age, but nuts, bananas, dried or preserved fruits (except when

(Continued at foot of opposite page).

THE DISTRIBUTION OF INDIAN TICK TYPHUS WITH NOTES ON LABORATORY FINDINGS

By H. E. SHORTT

LIEUTENANT-COLONEL, I.M.S.

and

ASSISTANT SURGEON H. A. H. D'SILVA, L.R.C.P.,
M.R.C.S., I.M.D.

INTRODUCTION

PREVIOUS to the world war which commenced in 1914, there was very little knowledge of the typhus-like fevers—apart from the classical louse-borne epidemic disease—except in the case of Rocky-Mountain spotted fever. The numerous and extensive outbreaks of typhus during the war in various countries, both of the West and the East, led to intensive study of this disease and its vector the louse. This study led, not unnaturally, to the recognition of other clinical entities, resembling the classical typhus in some of its manifestations, but obviously existing under conditions which precluded the usual rôle of the louse as a vector. Such typhus-like diseases have been described from every continent and are evidently of world-wide distribution.

Since they differ in their clinical manifestations from one another and from classical typhus only slightly, or in degree of severity, it is natural that they should be grouped together as the 'typhus group' of diseases. On their further classification, however, there is considerable difference of opinion and various systems have been advocated. That there should be some attempt at classification is important, since, while treatment may vary little, attempts at prevention or eradication are obviously closely bound up with the method of spread of each type and this, again, is entirely dependent on the arthropod vector. These considerations fully justify Megaw and Rao's (1928) criticism of Goodall's (1927) suggestion that these diseases are all 'typhus fevers pure and simple'

(Continued from previous page)

stewed) should never be allowed. Tea should not be allowed before the age of five, though the merest drop in the milk can do no harm and will please the child. Alcoholic liquors in any form, except when prescribed as a medicine, should never pass the child's lips.

Among other articles to be avoided may be mentioned: Jams with pips or seeds, coarse oatmeal and fruit having hard fibres, such as pineapple.

Most children dislike fat and it should not be forced on them as the necessary content of the food is already provided.

Chocolates and sweets in moderation may be allowed immediately after meals, but they should not be given between meals.

and that there is no need for further differentiation. The world-wide prevalence of typhus-like fevers, apart from certain proved findings, make it certain that the same vector, or even type of vector, is not responsible for the transmission of all members of the group and that, therefore, from the point of view of prevention or prophylaxis some classification is necessary. This is so obvious that the point need not be further stressed. While admitting, therefore, the necessity for some classification, it is not easy to decide on the most satisfactory basis for this classification, since the data for any particular system are as yet inadequate. This subject will be reverted to in a subsequent section.

As regards the typhus-like fevers in India, the first to call attention to these was Megaw (1917) who described an attack of fever from which he himself suffered and where there was a strong presumption that a tick was the vector. He also drew attention to the close similarity between his case and the fever investigated by McKechnie in the Kumaon Hills, the same area in which Megaw himself had been infected, and concluded that they were the same disease or, at least, diseases belonging clinically to the same typhus group. Since then many cases of the same disease have been reported from various parts of India and it is with a view to bringing before the medical profession in India the distribution of these cases that the present account has been written. It is hoped thereby that the recognition of the disease and the search for the vector or vectors may be stimulated since the vector may be different in different parts of and at different elevations in the sub-continent of India.

DISTRIBUTION OF CASES

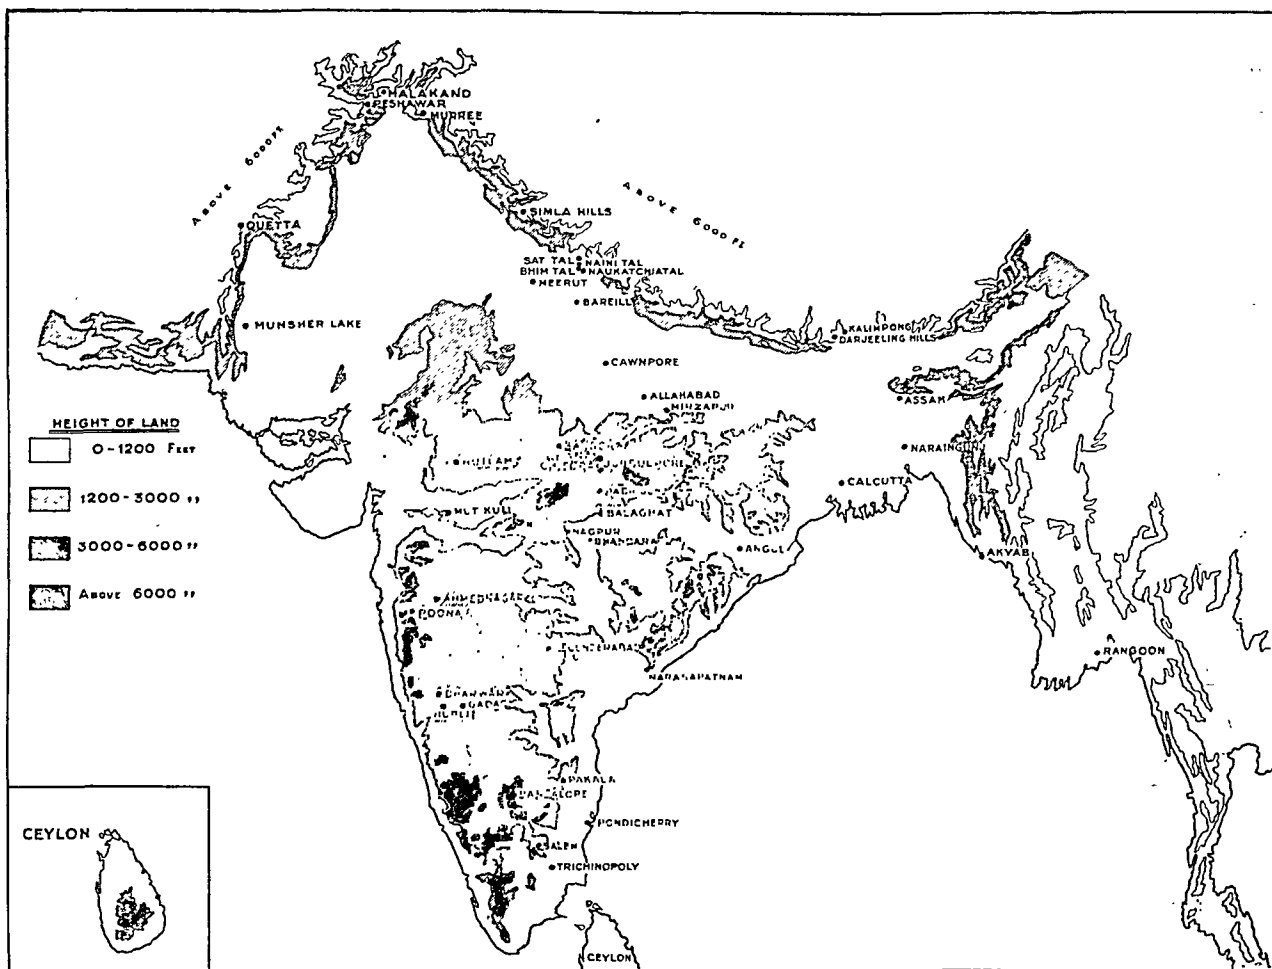

The distribution of cases can be shown most conveniently by a combination of a list of localities of recorded cases with a sketch map showing the approximate elevation of these places (see sketch map). The factors of locality and elevation must be considered together since climate, which must affect the vector or vectors, is largely affected by these two factors. Thus the cold weather in the plains is roughly equivalent to the summer in the hills, and it is, therefore, interesting and instructive to note that there is a general tendency for cases of the typhus group of fevers to occur in the summer time in the elevated parts of the country (4,500 to 6,000 feet) and in the winter season in the plains. Any search for a vector or vectors would have, therefore, to take into consideration factors such as these climatic requirements. The recorded cases of typhus-like fevers in India are summarized below according to localities, together with certain other details.

From table I it will be seen that there are 177 recorded cases of fever corresponding to the type we have called typhus-like fevers. Among

these there is a definite history of tick bite in 16 cases. It will also be seen that the distribution of the cases is India-wide. A third observation, which is equally evident, is that the cases occur throughout the year but this observation, on analysis, has to be modified. It will be seen that the cases may be classified into those occurring in the summer months and those occurring in the winter months. These two classes correspond very exactly with places which have a moderate climate (so far as temperature goes) at these two periods. In general terms elevated situations with relatively cool

has been given by Macnamara (1935). As regards the Weil-Felix reaction this was positive for *B. proteus* OXK suspensions in all the cases (16) except two, one fatal case of doubtful diagnosis and one case which gave a reaction with proteus X19 to a titre of 1:5,000. The latter case has not been published. The titre in the cases positive to OXK suspensions varied from 1:150 to 1:25,000. Unfortunately we were only able to study the last four cases, two of which were already in the later stages of their attack. From these cases blood was obtained and inoculated into a series of animals.

MAP

summer climates show cases in the summer months while plains areas with relatively cool winter climates show cases in the winter months.

TICK TYPHUS IN THE SIMLA HILLS

For some years it has been usual during each rainy season for a number of cases of tick typhus to be admitted to the British Military Hospital in Kasauli. During 1933, there were about a dozen cases. In 1934 there were more than this number, admitted both from Kasauli itself and the neighbouring hill stations Subathu and Dagshai. A clinical account of these cases

ANIMAL EXPERIMENTS

About 120 animals in all were used in these experiments including guinea-pigs, white rats, rabbits, mice and a squirrel, but, as the animal inoculations gave somewhat inconclusive results, we consider it unnecessary to describe them in full detail and only the salient points will be considered. It should first of all be noted that the regular passage of the infection from animal to animal in series, with presence of rickettsia, as noted in some of the typhus group of diseases in other parts of the world, was not seen.

It is notoriously difficult to be certain as to whether apparent departures from the so-called

normal temperatures in animals are really indications of an infective process, and therefore the temperature charts are not particularly informative. Under the circumstances it is unnecessary to give them in detail and only a few are produced to illustrate special points.

Guinea-pigs.—If the guinea-pig's normal temperature be taken as between 101°F. and 102°F., 26 out of a total of 28 guinea-pigs showed no marked fluctuations above or below this level, although the minimum and maximum levels represented a difference of at least five degrees. Two guinea-pigs, however, both inoculated intraperitoneally with blood from the same case, suffered from what appeared to be a definite febrile attack, commencing about 14 days after inoculation. The normal temperature of these guinea-pigs was between 100°F. and 101°F. by the thermometer in use. The charts (I and II) are given below. It will be seen that one of the animals had a preliminary rise on the 9th day. Neither of the animals suffered from any enlargement or evident inflammation of the testicular region, but, unfortunately, no further

investigation of these animals was carried out at the time.

Rats.—These animals, on the whole, appeared to give the best evidence of a definite infective process after inoculation, but this was limited to the primary inoculation of patients' blood and subpassage gave very indefinite results. Out of 8 primary intraperitoneal inoculations of blood into rats from four human cases 6 rats showed a definite febrile reaction after incubation periods of 9, 9, 6, 7, 12 and 7 days, respectively. Three typical charts (III, IV and V) are given below.

It will be seen that the temperatures during the febrile period are in the nature of more marked oscillations than those normally found rather than a prolonged higher temperature.

Rabbits.—Three rabbits only were inoculated from two human cases. Two showed no reaction but one showed a febrile reaction commencing eight days after inoculation and lasting for six days. The temperature chart is given below.

Mice.—Temperature records of the mice were not maintained.

(c) Congestion with œdema, sometimes marked, of the tunica vaginalis.

PATHOLOGICAL AND SEROLOGICAL FINDINGS
IN ANIMALS

Guinea-pigs.—(1) The pathological changes in inoculated animals were inconstant but a few showed the following changes:—

- (a) Enlargement and congestion of the spleen.
- (b) Marked congestion of the suprarenal capsules.

(d) The presence of organisms morphologically resembling *rickettsia* in smears from the tunica vaginalis.

(2) The sera of thirteen of the experimental guinea-pigs were each tested twice at various times after inoculation for agglutination against proteus OXK, OX19 and OX2 emulsions but in only one case was there any serological response shown. This guinea-pig showed

CHART V

Rat

CHART VI

Rabbit

agglutination with OXK in a dilution of its serum of 1 in 50. The remainder showed either no response or agglutinated OXK in a titre of 1 in 25, a result commonly obtained with normal guinea-pigs.

Rats.—(1) The infected rats showed the following pathological changes:—

(a) Enlargement and congestion of the spleen.
(b) Marked congestion of the suprarenal capsules.

(c) Congestion and oedema of the tunica vaginalis with, in one case, a testicular abscess, containing a mixed bacterial infection.

(d) The presence of organisms morphologically resembling *rickettsia* in smears of the tunica vaginalis.

(2) The sera of eight of the infected rats were tested for agglutination against proteus OXK, OX19 and OX2. The results of these tests are given in table II.

TABLE II

Rabbits.—(1) The three rabbits experimented with showed no signs of illness, apart from a

febrile reaction in one, and were not examined for pathological changes.

(2) One rabbit out of the three used gave a distinct agglutination response to emulsions of OXK with a rapid rise in titre in the course of six days. This, however, was not the rabbit which showed a febrile response. The results given by the rabbits are shown in table III.

SEROLOGICAL INVESTIGATIONS

The sera of certain laboratory animals and of wild rodents were examined. The latter gave results of some interest.

We had frequently heard old residents of Kasauli remark on the fact that the grey palm squirrel (*Sciurus palmaris*) was a new addition

to the fauna of Kasauli. They were said not to have existed there until a few years ago when they were introduced for experimental work at the Pasteur Institute of India, Kasauli. That this is probably correct is also shown by the fact that they have gradually extended their range in Kasauli in a north-to-south direction from the Pasteur Institute, which occupies the extreme north point of the cantonment. Now, as it was stated that the cases of tick typhus were also a new phenomenon, it occurred to us to consider any possible changes in the local fauna, and the question of grey squirrels immediately suggested itself to us.

We therefore trapped a considerable number of these squirrels from the Pasteur Institute estate, where one case of tick fever had just occurred and examined these from the serological point of view. Their sera were put up against O suspensions of proteus XK, X19 and X2—alcoholized, standardized suspensions were used and Dreyer's technique—4 hours in a water bath at 52°C. and incubation at 37°C. overnight.

In all but five instances the results were entirely negative with proteus OX19 and OX2. The results of these five exceptions are given below :—

Serial number	OXK	OX19	OX2
14	50	..	25
22	25	..	25
40	125	25	..
48	50	25	..
64	25	25	..

However, with OXK, 36 out of 65 were positive in dilutions of 1 in 25 or more, 3 being positive in a dilution of 1 in 125 and 16 in a dilution of 1 in 50. These results are especially interesting in view of the fact that all the local cases of tick typhus, with one exception, had shown reactions to the same strain, proteus OXK.

To control these results we next obtained approximately the same number of squirrels from plains areas (Ambala and Saharanpur) and tested the sera of these against the same strains. The results are in striking contrast to those obtained with the Kasauli squirrels. In the case of the plains squirrels only 12 out of 62 showed any agglutination against the OXK strain, two showed agglutination against OX19 and none against OX2. The two showing agglutination against OX19 are shown below :—

Serial number	OXK	OX19	OX2
58	25	25	..
61	250	125	..

The results of the agglutination with OXK in the two series are shown in the table below :—

TABLE IV

Results of agglutination tests with serum of squirrels from two sources, against an O suspension of proteus XK.

1 in 50 trace ..	6	1
1 in 50 ..	10	2
1 in 125 ..	3	..
1 in 250	1
TOTAL ..	65	62

The significance of the great contrast in these two batches of squirrels is not evident, but, since the agglutination was given only against the same organism which gave positive tests in the human cases, the fact is worthy of notice for further investigation, especially inasmuch as the entomological findings, to be later mentioned, showed a similar marked contrast in the two sets of squirrels. Besides the squirrels other rodents, as well as a few dogs, were examined serologically and the results are given without comment in tables V, VI and VII

When experiments were performed with this sterile venom solution and under strictly aseptic conditions, it was found that no hæmolysis took place even in the case of the cobra venom which is so strongly hæmolytic. Passing the venom solutions through the Seitz filter has, therefore, the effect of eliminating the hæmolysing fraction completely from the venom. The details of the experiments are set forth in the table.

From the table it appears that cobra venom has lost the power of hæmolysis altogether by being passed through the Seitz filter. The same experiments were repeated with red blood corpuscles obtained from guinea-pigs with almost identical results. Unfiltered cobra venom solutions in concentrations of 1 in 20,000 and 1 in 40,000, however, completely hæmolysed red blood corpuscles obtained from guinea-pigs within 10 minutes, whereas with human red blood corpuscles only a partial hæmolysis took place under those conditions, showing that the former are more susceptible to hæmolysis by cobra venom than the latter.

The next point to ascertain was whether the hæmolytic element was altogether eliminated by being passed through a Seitz filter or was merely inactivated by this process. It is a well-known fact that both cobra and Russell's viper venom which would not ordinarily hæmolysed red blood corpuscles obtained from sheep would do so in the presence of a very small amount of lecithin. The experiments in group (3) of the table will show that lecithin had no effect whatsoever on the filtered venom solutions with respect to hæmolysis.

The same experiments, when repeated with venom solutions that were not passed through the Seitz filter, gave the usual results. Both cobra and Russell's viper venom hæmolysed sheep's red blood corpuscles very readily in the presence of lecithin, as will be seen from group (3) of the table.

Experiments were also made to test whether the venom solutions had undergone any change with respect to their proteolytic activity by this process of filtration. It was found that with respect to the properties of dissolving fibrin, the liquefaction of gelatine and also the clotting of milk (rennetic activity) these venoms retain their activity almost unimpaired after filtration through a Seitz filter. Analysis was also made with respect to the protein constituents of the filtered and unfiltered venom solutions but no marked difference could be observed between them.

Pharmacological action.—In order to see whether, corresponding to the loss of hæmolytic property, the filter-passed venom solutions have suffered any change in their pharmacological characteristics, a female cat weighing 1,517 grammes was anæsthetized with urethane and given successively four doses of 0.5 c.cm. of 0.1 per cent venom solution in normal saline, as shown in the table below.

Venom solution	Blood pressure	Respiration
1. Cobra (unfiltered).	Small but maintained rise.	Transitory dilatation of bronchi followed by sudden return to normal and very slight increase in amplitude and rate.
2. Do. (Seitz filtered).	No effect.	Slight increase in rate.
3. Russell's viper (unfiltered).	Marked and permanent fall.	Sudden increase in amplitude and rate showing constriction of the bronchi and stimulation of the centre followed by respiratory irregularity and spasmodic breathing.
4. Do. (Seitz filtered).	Slight maintained rise.	No effect.

With respect to the cobra venom the vascular effect is altogether absent in the filtered solution but no such marked change was observed as regards the respiratory effect. With the Russell's viper venom, however, we find that there is a marked change with respect to both these actions.

Discussion.—The results mentioned above suggest that by the process of filtration through Seitz filters either the hæmolytic element has been altogether eliminated or it has been inactivated in such a manner that it is incapable of being reactivated by lecithin. The former hypothesis appears to us to be the more probable one, as Houssay (1921) found that the hæmolytic substance of snake venom is absorbed by animal charcoal, the residual venom solution being non-hæmolytic. We believe that with the Seitz filter also a similar process of adsorption is responsible for the loss of hæmolytic property.

Experiments are in progress with a view to ascertaining the nature of this hæmolytic principle and also how far this process of filtration through Seitz filters affects the other properties of the venom solutions.

SUMMARY

1. Passing of the venom solutions (cobra and Russell's viper) through the Seitz filter renders them non-hæmolytic.
2. The Seitz-filtrate of venom solutions are not reactivated by lecithin.
3. In the filtrate from cobra venom solutions the vascular effect is altogether absent, the respiratory effect being only slightly affected, whereas in the case of Russell's viper venom filtration through a Seitz filter has a marked effect on both these properties.

AN INVESTIGATION ON THE EFFECTS OF EVIPAN SODIUM ON THE BLOOD SUGAR OF THE RABBIT

By S. PRASAD

and

BARID B. SEN*

(From the Department of Physiology, The Prince of Wales Medical College, Patna)

THE sodium salt of cyclohexenylmethyl-N-methyl barbituric acid (evipan sodium) is a comparatively new basal anæsthetic. It is supposed to have the property of inducing surgical anæsthesia for short periods of about 15 to 20 minutes. It has a wide margin of safety and so it has gained considerable popularity as a general anæsthetic in surgical procedures of short duration.

Anæsthetics in general have a considerable effect on the blood sugar. So far as the drugs of the barbituric acid group are concerned, contradictory results have been reported. While anæsthetic doses of barbiturates, according to some observers, cause no change in the blood sugar level of normal fasting animals, others have found marked hyperglycæmia, *e.g.*, Underhill and Sprunt (1927) with amytal on the rabbit, Weiss (1926) with amytal, medinal, and sodium iso-allyl propyl-barbiturate on the cat and the dog, and Bang (1913) with veronal on the rabbit. Kennedy and Narayana (1934) working with sodium evipan found no appreciable effect on the blood sugar in doses varying from 45 to 90 milligrammes per kilogramme of body weight in the guinea-pig and 40 to 100 milligrammes per kilogramme of body weight in the rabbit.

Considering the fact that other barbiturates do produce hyperglycæmia, as some experimenters report, we thought fit to reinvestigate whether this new anæsthetic, *i.e.*, evipan sodium, which also belongs to the barbituric acid group, has any effect on the blood sugar.

TECHNIQUE

Blood sugar estimation was done by Maclean's method which has given very satisfactory results for the last few years with one of us (S. P.).

Rabbits were employed all through the present observations. Blood samples were collected from the ear veins, the animals being treated with great gentleness so as to ensure as little excitement as possible. The anæsthetic was always prepared fresh and injected intraperitoneally in 5 per cent concentration.

The rabbits were starved overnight and experiments were carried out early next morning. The dose used, generally, was 60 milligrammes per kilogramme of body weight, but lower and higher doses, *i.e.*, 40 and 80 milligrammes per

kilogramme, were also employed. Blood sugar was determined at intervals of half an hour for 2 to 3 hours. In some cases earlier samples were also taken. Control experiments were done by injecting saline intraperitoneally and the results were also confirmed by repeating the same experiment on each rabbit twice at intervals of 4 to 5 days.

RESULTS AND DISCUSSION

Soon after the injections of the evipan sodium in anæsthetic doses the animals began to shiver, respiration became hurried and their eyes rolled up and down. After a temporary period of restlessness, the animals became quiet and would lie down with the muscles relaxed. Some of the animals exhibited slight retraction of the head and opisthotonos. With a dose of 60 milligrammes per kilogramme of body weight hypnosis came on within 3 to 5 minutes and lasted on an average for 50 minutes. With a dose of 80 milligrammes per kilogramme the respiration was slowed down considerably and hypnosis came on within 2 minutes and lasted longer. Malloney and Hertz (1935) found that 60 milligrammes produced hypnosis 3 minutes after injection and this lasted for a period of 44 minutes on an average.

Blood sugar estimations of the rabbit under observation before and during anæsthesia showed a distinct rise as will be evident from

GRAPH

Rabbit, male, weight 1.66 gm.

The curve shows the effect of injecting 100 mgm. evipan sodium. The injection was given at the arrow mark.

the table below. The table shows the pre-anæsthetic blood sugar percentage, and the average blood sugar percentages during anæsthesia and recovery. In one experiment, however, instead of the usual rise, a fall in the blood

* Patna University Research Scholar.

sugar was noticed with a dose of 60 milligrammes per kilogramme. This was probably due to a high initial blood sugar level as a result of excitement.

It will also be seen that with a dose of 40 milligrammes per kilogramme of body weight the increase in blood sugar above the fasting level was about 9 per cent on an average; with a dose of 60 milligrammes per kilogramme the rise was about 22 per cent in a majority of experiments, although a group of 6 rabbits exhibited an average rise of even 50 per cent over the fasting level.

TABLE

Evipan sodium in mgm. per kgm. of body weight	BLOOD SUGAR IN MG.M. PER CENT

60	120	150	120
60	68	75	70
60	68	82	72
60	75	110	110
60	80	120	110
60	70	98	80
60	78	110	101
60	87	145	115
60	70	113	..
60	112	100	87
60	81	145	137

It was further found that the rise in blood sugar was evident half an hour after the injection, the highest level usually being attained in about an hour. Earlier samples did not exhibit any appreciable change. After an hour, the blood sugar began to fall gradually, returning to its normal level, generally, in 2 to 2½ hours from the time of injection of the anaesthetic. The curve in the graph is from a typical experiment; it shows that there was no rise for 15 minutes after the injection, the highest rise was obtained an hour after the injection and the blood sugar returned to the pre-anaesthetic level 2½ hours after the injection of the anaesthetic.

Evipan sodium thus behaves like the other drugs of the barbituric acid group in raising the blood sugar although Kennedy and Narayana (1934) report no change. Since the majority of workers have found increases in blood sugar with different barbiturates, it is quite probable that evipan sodium in common with the other barbiturates also raises the blood sugar. Regarding the mechanism of the rise in blood sugar it is probable that the sugar is released

FLUORESCEIN IN LEPRO REACTION

By A. T. ROY, L.M.F.

Assistant Medical Officer, Purulia Leper Colony
and

G. R. RAO, D.T.M. (Cal.)

Assistant Medical Officer, Purulia Leper Colony

INTRODUCTION

THE beneficial effects obtained by the use of 'Mercurochrome-220 soluble', a fluorescein compound of mercury, in leprosy cases, especially in prolonged lepra reactions, in arthritis of leprosy as well as of undetermined origin, and in *Bacillus coli* septicæmias, etc., were first recorded in India, by the present writers in Rao and Ray (1932). Since then, other workers, notable among them being Muir and Chatterjee (1932 and 1933) and Chatterjee (1933), have attempted to study the action of Mercurochrome as well as that of one of its constituents, viz, fluorescein, in leprosy. Ryrie (1934) has further continued to study the influence of fluorescein on 'lepra reaction', and has concluded that in a fairly large proportion of such reacting cases, fluorescein appears to be beneficial.

In view of the favourable opinion expressed by Ryrie and also in view of the fact that we occasionally come across cases of prolonged reactions which are not much benefited by any accepted routine treatment, such as hospital regime, with potassium antimony tartrate injections supplemented by calcium therapy and salicylates by the mouth, etc., we thought it

(Continued from previous column)

from the liver as a result of liberation of adrenalin from the suprarenal medulla or by producing a disturbance in and around the thalamus as has been suggested by Weiss (1926) in the case of amytal.

SUMMARY

Evipan sodium in anaesthetic doses raises the blood sugar of the rabbit.

ACKNOWLEDGMENTS

We have to thank Professor Narayana, on whose suggestions and advice the observations were carried out. We have also to thank Havero Trading Company, Limited, Calcutta, for the supply of evipan sodium free of cost.

better to give a thorough trial of fluorescein, in reacting cases, with a view to assessing its merits *vis-à-vis* those of potassium antimony tartrate and other anti-reaction remedies in use at present, in the hope of discovering in fluorescein a valuable alternative method of treatment that could be adopted in cases which do not derive any benefit from other anti-reaction measures.

MATERIAL FOR STUDY

In this colony which contains more than 800 inmates of all types of leprosy, and where about 2,000 outpatients attend our outpatients' clinic every month for treatment, there is no dearth of lepra-reaction cases. But in the

the upward trend of the curve, as signifying a reaction. Others include even periodical nerve pains or myalgic pains in the category of lepra reactions. There seems to be no uniformity of opinion about what essential features should be present in a case, before it may be considered as reacting. Our present-day inadequate knowledge of the pathology of reactions, as well as their exact prognostic significance, no doubt contributes to this sort of loose thinking on the subject. We have therefore considered it necessary, at the outset, to define what we mean by reactions, as in the absence of such clear definition, any case of leprosy neuralgia or myalgia, or clinically observed advancing cases, are apt to be included amongst 'reacting

CHARTS 1 TO 4

interest of scientific accuracy we thought it better to confine our experimental treatment with fluorescein to our inmates only, as we have a fairly correct record of their antecedent illnesses, they live under controlled conditions in this institution and we are more in personal touch with them than with our outpatients. All cases of reaction that did not subside within four or five days of the onset were considered as severe reactions deserving hospitalization, and were admitted into the hospital.

In this connection we cannot help observing that there appears to be a great deal of confusion about what constitutes a lepra reaction. Some writers consider any appearance of small new lesions, in cases that are obviously on

cases' and entirely fallacious results claimed on behalf of the particular drug employed in such cases.

All cases showing fever of not less than a week's duration, the temperature rising moderately high, with the exacerbation of old existing lesions, and the formation of fairly numerous clinically-well-recognizable new lesions, with signs and symptoms indicative of constitutional disturbance, such as vomiting, diarrhoea or constipation, vertigo, anorexia and drowsiness, were considered as fairly severe reactions deserving admission into the hospital. Such a comprehensive standard had to be adopted for two reasons:—(1) Cases of mild reaction, such as those with fever of three or

four days' duration, the temperature not exceeding 101°F. or 102°F., with very few new lesions appearing, without exacerbations of the old lesions, and without signs of clinically recognizable constitutional disturbances, could be treated in their homes. Such cases could not be admitted into the hospital because of want of accommodation. Further, our experience here, as well as elsewhere, during the last eight years, has shown that such cases recover from their reaction naturally, without any kind of special treatment. (2) To study the influence of any new drug in such cases would be tantamount to self deception. If fluorescein has any beneficial effect at all on lepra reactions it would be manifested in well-marked lepra reaction cases that would not be affected merely by either a hospital regime, a dose of salts, or psychotherapy. And the reported beneficial influence should manifest itself in all cases of reaction of the same degree, irrespective of the rate or sex of the individual treated.

Twelve well-marked cases of fairly severe lepra reaction, conforming to our standards of severity enumerated above, were admitted into the hospital in the course of the first half of the year 1934 for observation and treatment. Nine of these were treated with ten cubic centimetres intravenously of a two per cent solution of Grublers' fluorescein (water-soluble), twice a week, or in a few cases, three times in two weeks, depending upon the tolerance of the patients and the response obtained, keeping a close watch on the temperature and erythrocyte sedimentation index which was determined, as a rule, just before administering the next dose of fluorescein. The sedimentation test was done weekly, even after the temperature reached the normal, with a view to ascertaining whether fluorescein had any delayed beneficial influence on the natural resistance factor. The usual technique was used in carrying out the erythrocyte sedimentation test, by taking the average of two readings of the first and second hours.

The required quantity of fluorescein solution was prepared freshly each day, just before use, and the injections were given by one of us (A. T. R.). The remaining three cases served as controls. One was treated with intravenous injections of potassium antimony tartrate on alternate days, four cubic centimetres of a one per cent solution in physiological saline, prepared freshly just before use, being the dose injected. The second was treated with plain physiological saline intravenously in four cubic centimetre doses. The third did not receive any special treatment excepting the routine hospital diet and care. In fact, the hospital regime was a common factor in all cases.

To exclude the possibility of errors introduced by other concomitant illness such as malaria, influenza and other febrile diseases, cases about which we had the slightest suspicion, were excluded from this experimental study. Thus,

every care was taken to assess the real value of fluorescein in uncomplicated well-marked lepra-reaction cases.

RESULTS

A glance through the temperature charts of the nine cases treated with fluorescein shows that after two to four injections of fluorescein, the temperature showed a tendency to return to the normal, thus confirming, partially, the opinion of Ryrie (*loc. cit.*). But a comparison of the charts of these cases with those of the three controls shows that, in the latter also, the same tendency of the temperature to return to normal was manifested. This tendency can be explained by the supervention of the debility factor impairing the reacting power of the individual. To confirm this explanation we have, first, the erythrocyte sedimentation index curve shown by a dotted line on the charts. A comparative study of this curve with that of the temperature clearly brings out the fact that though the temperature comes down after two or four injections of fluorescein, the sedimentation index still remains high, and shows no such rapid tendency to come down. It is a matter of common knowledge amongst leprosy workers of experience that a persistent high sedimentation index means prolonged debility. Second, we have the reported dangerous toxicity of fluorescein to experimental animals (Emerson and Anderson, 1934), which toxicity is very probably instrumental in precipitating the onset of the debility factor in human beings.

Fluorescein seems to have no favourable effect on the natural resistance factor and our observations indicate that it brings down the reaction (a) by a probable anti-pyretic effect, and/or (b) by hastening the onset of the debility factor, which, in control cases, as well as in untreated natural lepra-reaction cases, ultimately brings down the reaction. Comparing the first nine charts with those of the three control cases, we do not find any special noteworthy effect obtained by the use of fluorescein; and we have therefore to conclude that it possesses no particular advantage over potassium antimony tartrate, or other routine methods of anti-reaction treatment. In cases which are particularly susceptible to potassium antimony tartrate, or do not respond to other measures, fluorescein may be used.

SUMMARY AND CONCLUSIONS

(1) An experimental trial of fluorescein has been reported on in nine well-marked lepra-reaction cases with three control cases of similar reactions treated by (a) potassium antimony tartrate, (b) physiological saline, and (c) no special treatment, all the 12 cases being kept under hospital regime.

(2) A comparative study of the temperature charts of these cases shows that while two to four injections of fluorescein have an undoubted

anti-pyretic effect, no beneficial effect on the erythrocyte sedimentation index, which is a measure of the natural resistance, is evident. On the other hand, the latter continues to be high, indicating a prolonged debility.

(3) Even in the three control cases untreated with fluorescein, the same tendency to reach normal is shown by the temperature chart; and the same tendency to remain high is shown by the sedimentation index.

(4) These facts lead us to conclude that fluorescein has no particular advantage over potassium antimony tartrate or other routine methods of anti-reaction treatment, in use at present, and that it probably brings down the temperature by (a) an anti-pyretic effect and/or (b) by virtue of its toxic action hastening the onset of the debility factor which ultimately brings down a lepra reaction in untreated cases.

(5) We are of the opinion that fluorescein can be used as an alternative method of treatment in cases which do not tolerate the potassium antimony tartrate well or which do not respond to any other routine anti-reaction treatment.

ACKNOWLEDGMENT

Our grateful thanks are due to our assistant, Babu Andrew Bansriar, who helped us with the sedimentation tests and the drawing of the charts.

[Note.—This paper is of value only as conveying the impressions of two experienced leprosy workers. From a statistical point of view the lepra reactions are far too variable to allow conclusions to be drawn as to the value of any form of treatment unless at least 100 cases were included in each group.

The authors sent us 12 charts, but we are only able to include 4 of these. The charts can be analysed shortly as follows:—

In the fluorescein series, two cases remained febrile throughout the period of observation, 48 and 51 days, and in the others the temperatures subsided on the 40th, 14th, 11th, 9th, 7th, 6th and 5th days, respectively.

In the control cases it subsided on the 26th, 17th and 5th days, respectively.

The sedimentation index in the fluorescein series was low from the outset in one case, in 3 it remained high throughout, and in the rest it fell appreciably by the 62nd, 28th, 23rd, 15th and 13th days, respectively.

In the control series it remained high and unchanged in 2 cases and fell appreciably on the 42nd day in the other case.—EDITOR, I. M. G.]

HETEROTOPIC BONE IN ELEPHANTOID TISSUES

By M. M. CRUICKSHANK

LIEUTENANT-COLONEL, I.M.S.

General Hospital, Madras

Miss P., an Anglo-Indian lady, age 32 years, a resident of Malabar, was admitted to hospital on the 15th September, 1934, suffering from a gross condition of elephantiasis of both legs.

The swelling of the legs began 20 years ago and since 1923 the patient had suffered from attacks of fever with occasional rigors about once a month. During these attacks the legs became very painful and she was unable to get about.

Examination revealed enormous swelling of both legs with two large round masses of elephantoid tissue on the anterior and posterolateral aspects of the left leg near the ankle. The swelling on both legs was hard and indurated, allowing of no pitting on pressure. X-ray examination showed numerous, irregular and discrete areas of calcification scattered over the lateral aspects of both legs.

On the 20th September, my assistant, Mr. N. S. Narasimhan, F.R.C.S., excised the two local swellings on the left leg and removed strips of deep fascia. On the 2nd November and on the 12th November, I performed Kondolón's operation on the right leg, first on the medial then on the lateral aspects through incisions extending from the knee to the foot, and on the lateral aspect on to the dorsum of the foot. At these operations the deep fascia was found to be about $\frac{1}{4}$ inch thick, cutting almost like cartilage, and in it, on removal, could be demonstrated the calcified areas seen in the x-ray films and in addition areas of new bone formation, verified by microscopical examination, mostly situated in the fascia over the tibialis anticus.

One might add that all the deep fascia was completely removed from the knee to the ankle in the whole circumference of the right leg. The first operation affected the patient not at all; the second was attended with a degree of shock, which necessitated intravenous glucose-saline therapy. The patient is now able to get about comfortably, but the present improved condition is in a measure due to the removal of large amounts of elephantoid skin. It is too near these operations to speak of any lasting beneficial effects, but unfortunately my experience of Kondolón's operation has not been that of unqualified success.

Sir Harold Gillies is probably right when he considers that the lymphatic block lies in the inguinal glands and that these must be side-tracked if success is to be assured.

The chief interest in this case lies in the presence of heterotopic bone in the thick, indurated deep fascia. Development of bone in tissues remote from the skeleton is a rare but interesting process.

Heterotopic bone arises in connection with fibrous connective tissues in a state of functional disuse or death. The origin of the bone was formerly attributed to the activity of osteoblasts derived from distant sources. MacEwen conjectured that the heterotopic bone formation was due to the migration of osteoblasts from the blood stream into injured tissues, whilst ossification in the abdominal wall was attributed to injury of the xiphisternum or pubis at operation, with consequent liberation of osteoblasts. But osteoblasts may be absent from the area of new bone formation and the osteoblast or fibroblast is not essential for the formation of new bone.

According to Leriche and Policard any tissue, before it can exchange its identity, must be reduced to its primordial condition, must be de-differentiated to mesenchyme and then undergo a redifferentiation. From this primordial mass of liquefaction to which any connective tissue may be reduced, there may develop fibrous tissue, cartilage, or bone.

It is laid down by Leriche and Policard that bone formation is dependent upon an ossifiable medium, a sufficient blood supply and an adequate supply of calcium.

Pathological calcification is common in old tuberculous lymph nodes, in costal cartilages, in semilunar cartilages, in intervertebral discs, and in avascular tissues where metabolism is low and where the metabolic rate may be further reduced as the result perhaps of injury or infection or both. A heterotopic deposition of calcium must precede the formation of heterotopic bone.

The first problem then is to account for the deposit of calcium in devitalized tissues, there-after the formation of heterotopic bone can be explained according to Greig on those principles laid down by Leriche and Policard. Greig states: 'the prelude to calcification is loss of function; calcification is a sign of utter uselessness, of functional death, but ossification is a sign of life, and the precursor of ossification is calcification. Under conditions of low metabolism calcium from percolating blood serum or lymph is deposited in crystalline form'.

But how can this pathological deposition of calcium in tissues be explained, where no evidence of hypercalcaemia exists, for instance in old tuberculous lymph nodes, in costal cartilages, in intervertebral discs, in coeliotomy scars, in fascia lata, and—as in the present case—in the deep fascia of elephantoid limbs?

The mechanism of the deposition of calcium is probably a physico-chemical one.

Robison invokes the aid of an enzyme, 'phosphatase', with, as in the case of most enzymes, a reversible action, one hydrolytic the other synthetic.

The action of this enzyme, which Robison points out is present in tissues, which normally become the site of calcareous deposits, depends

on the hydrogen-ion concentration of tissue fluids, on the concentration of calcium ions, and probably upon many other unknown factors.

The enzyme or phosphatase theory, which at the moment has most experimental backing, depends on the fact that certain cells in certain tissues can secrete an active enzyme, which hydrolyses the salts of phosphoric esters brought to the tissue in the circulating blood. This causes local increase in the concentration of phosphate ions, with the precipitation of a complex carbinato-phosphate molecule, the bone salt, in or near the cells which secrete the enzyme.

This enzyme according to Greig may be liberated by the death of fibroblasts and may facilitate the transference of calcium from the colloidal state in which it exists in the blood serum and lymph to the condition in which it is present in bone.

Huggins has shown by transplanting bladder epithelium into the abdominal wall of the dog, and thus producing heterotopic ossification, that the ossifying tissue possesses a high phosphatase activity. It is concluded therefore that calcification is the result of phosphatase activity in a tissue, in which exists a suitable concentration of calcium ions, in which the hydrogen-ion concentration is optimal, and probably in addition a balance of factors yet unknown.

But this fails to explain why calcium is deposited in avascular devitalized tissues where there is no evidence of hypercalcaemia.

Though the local circulation of blood and lymph in avascular tissues is almost at a standstill, yet that circulation, be it of blood or of lymph only, must play an important part in the deposition of calcium. The whole question of phosphatase activity is however still problematical. The calcium having been deposited, then the postulates of Leriche and Policard come into play. A relative hyperaemia, whether the result of irritation due to the calcareous deposits, or whether the result of infection, occurs, with an increased transudation of serum. Decalcification of the calcareous deposit takes place as a result of the relative hyperaemia or of the synthetic action of phosphatase. The local excess of colloidal calcium is now available.

The hydrolytic action of phosphatase now comes into play and with the cutting off of the relative excess of blood supply, which also may be the result of enzyme action, the colloidal calcium is converted into the form required by bone and new bone is laid down. But what was the hormonal or other disturbance which called the dead tissue to life, and for what purpose? The perennial puzzle remains for solution.

COMPOSTING OF TOWN REFUSE BY THE 'EDELMIST' PROCESS

By S. RAJAGOPAL
J. G. SHRIKHANDE

and

V. SUBRAHMANYAN

Department of Biochemistry, Indian Institute of Science, Bangalore

CONVERSION of organic wastes, including night-soil, into manures has been practised for a number of years. Among the methods so far developed, those of Hutchinson and Richards (1921), Waksman and co-workers (1927), Fowler (1930) and Howard and Wad (1931) are most extensively adopted. These methods involve fermentation under essentially aerobic conditions. They are fairly rapid, but they also involve serious loss of both nitrogen and organic matter. Repeated attempts to raise the level of organic nitrogen, at any rate under Indian conditions, in the fermenting heap by the aerobic processes have not so far met with much success. Besides this particular aspect which, no doubt, is the most important from the agricultural point of view, there are several others, pertaining to the hygiene of the disposal which need careful study, e.g., (1) prevention of fly-breeding and (2) maintenance of high temperature at least in the early stages to destroy pathogenic and putrefactive organisms. These points are of considerable importance where night-soil is added as the source of available nitrogen for the decomposition of town refuse. Attempts to improve the hygiene of disposal and prevention of fly-breeding by chemical sprays have proved

costly. Sometimes the chemical used may even have an adverse effect on the course of decomposition by a modification of the micro-flora.

Among the other methods, the 'Edelmist' (hot fermentation) process originally developed by Krantz [Cunningham (1927), Rusehmann (1927), Boetskaul (1927), Fruwith (1928)] is best known. It is claimed to be hygienic and economical in regard to both nitrogen and organic matter. Quite apart from the above considerations, the Edelmist process should be regarded as a decided advance on ordinary methods in that it affords a means of controlling the fermentation of the manure. It was considered desirable therefore to make a systematic enquiry into the possibility of applying this process to the disposal of town refuse in India. The process, in short, consists in allowing the compost heap to ferment aerobically till the maximum temperature is attained. It is then pressed and packed tightly and maintained under anaerobic conditions for three to four months after which the manure is ready for application to land.

The method is being examined critically under both field and laboratory conditions with a view to standardizing the condition by which the disposal will be hygienic and will, at the same time, give a good yield of manure of a high organic nitrogen content. The enquiry has been divided into two sections—decomposition of (1) refuse in big chambers under field conditions or in small jars under laboratory conditions, and (2) a plant material like ragi straw in bottles. Only a few of the more important results obtained in the field study have been included in the following table.

TABLE

Form of nitrogen added to refuse	RATIO OF CARBON TO NITROGEN BEFORE FERMENTATION											
	30 : 1				20 : 1				10 : 1

Ammonium sulphate.	86.4	1.50	1.53	1.79	83.6	2.30	2.22	2.49	82.0	3.5	3.00	3.62
Calcium cyanamide.	86.4	1.50	1.06	1.19	94.7	2.30	1.75	2.06	96.2	3.5	2.40	2.45
Sodium nitrate.	82.8	1.50	1.53	1.82	91.2	2.30	1.91	2.13	89.5	3.5	2.5	2.74
Night-soil	89.7	1.40	1.38	1.47

The results have been expressed as on 100 kg. of original material.

There was absolutely no smell at any time during the fermentation; nor was there any fly-breeding. The finished products—especially that originally treated with night-soil—had a pleasant earthy odour and crumbled readily to fine powder. In three of the sets there was complete recovery of nitrogen when the C-N ratio was 30 : 1 though there was some loss at the narrower ratios (especially at 10 : 1). In the latter case the loss was not entirely due to the formation of gaseous products. It was largely due to the heavy rains which percolated through the brick and clay walls and caused a part of the soluble salts to diffuse out. It may be noted, however, that the nitrogen contents of the finished products were higher than those obtained by the other methods in vogue. The losses in dry matter which are also below 20 per cent are lower than those obtained by the aerobic methods.

Experiments are in progress to further standardize the method; to determine the

optimum moisture content; to control the initial aerobic fermentation; to devise new types of cheap, water-proof cisterns; to compare the relative merits of fermentation in overground and underground pits; and to determine the best method of storing the finished product till it can be applied to land.

A Mirror of Hospital Practice

NOTES ON A CASE OF ACUTE LEAD ENCEPHALOPATHY

By G. K. RANADIVE, M.B., B.S.
Somwar Peth, Poona City

A YOUNG MAN, aged 20 years, a tailor by occupation, was admitted into the Sassoon Hospital, Poona, on the 17th July, 1935, for acute pain in the abdomen. It was suspected to be a case of 'acute abdomen', so he was admitted on the surgical side where on investigation it was found to be more probably a case of lead colic. There was a history that once in two or three months for the last five years the patient used to get attacks of pain in the abdomen. The last attack was characterized by a very severe pain of a spasmodic nature and which continued for a couple of days. The pain was so severe that it could only be relieved by an injection of morphia.

The man was transferred to the medical side, and though he was free from abdominal pain, he appeared to be very depressed. He was very slow in answering questions and at times showed confusion of ideas. Sometimes when spoken to, he would not take any notice, appeared to be in a trance-like state and showed fine tremors of his lips.

The patient was thin, slightly anæmic, pulse rate ranging between 112 to 140; tongue coated, bowels constipated, typical blue lines on the gums, there was occasional slight rise of temperature, blood for malaria parasites—negative, urine—normal. The red cells showed no punctate basophilia.

Three or four days after his admission to the medical ward, general paresis of the upper and lower limbs developed. He was then given an intramuscular injection of calcium gluconate on three successive days with the idea of removing lead from the general circulation. There was difficulty in collecting the urine earlier, hence the chemical examination of urine was done after the injections of calcium. No lead was detected in the urine. The general paresis became gradually more marked and the mental condition became worse. There were signs of polyneuritis: flaccidity of muscles, deep reflexes lost. Wrist drop and foot drop were present on both sides. If the forearms were placed in a

pronated position the patient could supinate them. There was a rapid generalization of paresis. The voice was affected (adductor paresis). The affection pursued a course like an ascending paralysis associated with a rapid wasting of all the muscles. Ultimately the patient died on 2nd August, 1935, as a result of paralysis of the diaphragm.

Report of the chemical examination.—Lead was positively detected in the cerebro-spinal fluid where traces could be found on spectroscopic examination.

Points of special interest in this case are:—

1. Acute plumbism is not attributable to any definite cause. The patient was a tailor and owing to his generally impaired health the contamination with lead might have taken place on account of his occupation. Tailors generally suck thread prepared with lead beeswax.
2. The abdominal symptoms were so severe as to warrant a diagnosis of 'acute abdomen'.
3. There was no punctate basophilia.
4. The urine was negative for lead.
5. In this case lead showed special affinity for the nervous system. The affection of the brain was indicated by the confused state of mind which gradually became worse. The generalized paresis was quite characteristic of plumbism though it simulated Landry's ascending paralysis to a great extent. The only confirmatory evidence of plumbism was found in the cerebro-spinal fluid.

I wish to thank Col. Candy, Civil Surgeon, Poona, for permission to publish these notes.

[The evidence on which the diagnosis in this case was based seems to be rather slender. The failure to find lead in the urine in such a severe case of lead poisoning is too remarkable to be dismissed lightly. The question of acute diffuse myelitis, also associated with ascending paralysis, does not seem to have been considered.—EDITOR, I. M. G.]

A CASE OF MALIGNANT TUMOUR OF THE STOMACH IN A MALE WITH TRANSPOSITION OF THE VISCERA

By F. R. W. K. ALLEN, M.A., B.Ch. (Dub.)
MAJOR, I.M.S.

Civil Surgeon, Raipur, Central Provinces

A MALE, aged 30 years, was admitted to the Main Hospital, Raipur, on 20th July, 1935. He was very emaciated and complained that for the last four months he had been suffering from vomiting and constipation. It was found that his heart was transposed and that he had a tumour in his left hypochondriac region. He was unable to retain a barium meal long enough for a satisfactory x-ray examination but it was evident that hardly any food was passing through the pylorus which was seen to be on the left side. He was not really fit for operation but after some hesitation in order to relieve his painful vomiting laparotomy was performed under rectal ether on 8th August. It was found that the lymphatic glands were involved to such an extent that gastrectomy would be of no avail even if he could survive such a severe operation. After verifying that he had complete transposition of his abdominal viscera an anterior retrocolic gastro-jejunostomy was performed and his abdomen was closed. During the operation and for twelve hours afterwards he was given continuous intravenous 10 per cent glucose in normal saline at 45 drops per minute. He never vomited again after the operation and his abdominal wound healed perfectly. By 15th August he was able to eat pounded fish and his bowels were moving. He continued to make satisfactory progress for five days. He then began to suffer from diarrhoea and later passed undigested food in his motions. To compensate for a reduction in his diet it was decided to give him a blood transfusion but no volunteer could be found. He began to go down hill and died on 28th August, three weeks after the operation.

A CASE OF PYO-PERITONEUM

By NUR MOHAMMAD, M.S.M.F.

Sub-Assistant Surgeon, In-charge Sahiwal Dispensary, Shahpur District, Punjab

S., a female, aged 30 years, pot-maker, was admitted into the hospital on 26th June, 1935, complaining of distension of abdomen, slight cough and extreme weakness for the last two and a half months.

History of the present illness.—Two and a half months back the patient woke early one morning with a very severe colicky pain starting in the umbilical region, and radiating all over the abdomen. The patient vomited twice. The condition subsided within about six hours and in the afternoon she felt a chill and developed fever which continued, and at the same time she developed a cough. After about three weeks, the patient noticed that her abdomen was slowly and steadily increasing in size. She then came for treatment.

Previous history.—No previous illness. She had had three children the last being born about nine months before the onset of her present illness.

Family history.—Nothing having any bearing on the present condition.

Physical examination.—The patient was weak and emaciated and could hardly walk about. She had pyorrhoea alveolaris and decayed teeth. The abdomen was distended and fairly tense but it moved fairly well with respiration. The superficial veins were distended and the caput medusae was well marked. The skin was dry and shining. There was no tenderness in any part of the abdomen. The fluid wave was very well marked across the abdomen. The flanks were dull on percussion and the dullness moved to the

dependent side on change of position. The heart, though weak and quick, was otherwise normal. The lungs showed signs of chronic bronchitis. The urine was quite normal. The temperature at the time of admission was 99°F. It ranged below 100°F.

Diagnosis and treatment.—The case was diagnosed as ascites and was treated on the usual lines for about a week but without any improvement. The abdomen slowly and steadily continued to increase in size and the patient complained of difficulty in breathing.

She was tapped on the 7th of July and thin greenish and very foul pus came out through the cannula. About five pints of the pus were drawn off, and the wound sealed with collodion. The patient did not improve after tapping. Her condition became worse and she died about 4 days afterwards.

Conclusion.—Clinically this case appeared to be one of cirrhosis of liver with ascites. There was no sign of any localized or generalized peritonitis, nor could any disease of the generative organs or spine be detected.

[The writer has not indicated the special circumstances that led him to adopt a line of expectant treatment when he found free pus in the peritoneal cavity.—EDITOR, I. M. G.]

EPHEDRINE, AND THE REDUCTION OF A STRANGULATED HERNIA*

By B. K. WADIA, M.B., L.O., B.S.C.

Calcutta

W. J., aged 28 years, suffered from a right-sided hernia since childhood but this gave him no trouble until a few months ago. One day, recently, the hernia was found to be irreducible.

When I saw him three hours later, he was trying to push the hernia up into the abdomen and applying ice. Taxis for half an hour failing to reduce it, I injected atropine 1/60 gr. Finding taxis and ice still ineffective, I gave atropine 1/30 gr. two hours after and also a warm soap enema at moderate pressure, the can being held at a height of about 2 or 3 feet and the bowel contents evacuated.

These measures were ineffective and the patient refused to go to the hospital, so I gave him a $\frac{1}{2}$ grain tablet of ephedrine, with the idea that from its direct action on the splanchnic system it might act where atropine failed. I repeated the dose six hours later. An hour later, only a small knuckle of gut could be felt in the hernial sac, and this was fully reduced on further taxis, 15 hours after strangulation had occurred.

On a previous occasion a month earlier, the hernia was reduced in two hours after a single injection of atropine, but the patient was attended to in a little over an hour after the occurrence of strangulation. This time, however, perhaps because of the longer interval before the patient was first seen, atropine combined with an enema and ice applications seemed to fail completely, but later ephedrine proved successful.

It is possible that ephedrine succeeded and atropine failed in this case because the former has a direct action on the sympathetic splanchnic nerves and produces a stronger inhibitory action on the bowel than the latter, which only acts indirectly on the sympathetic nerves by paralysing the opposing vagal nerve endings.

JANUARY

THE CONTROL OF THE DRUG TRADE

THE mills of government in India have the reputation for grinding slowly, but at the same time for grinding 'exceeding fine'. We do not know how far they are entitled to the latter part of their reputation—probably on the whole the claim has been justified—but no one will deny their slowness. There are times when a little more rapid, even if a little coarser, grinding would be welcome. The particular subject that we have in mind at the moment is the control of the sale and manufacture of drugs and the organization of the profession of pharmacy; for practical purposes they constitute one problem.

During the last half century, medical organization has advanced rapidly in India, medical colleges and schools have been built and are being run largely at government expense, thousands of medical men are turned out each year, and the standard of medical education is very carefully controlled by provincial medical councils and now by an all-India medical council. Public health organization developed later and is advancing less rapidly, nevertheless this has been advancing too, but pharmacy and the drug trade has been allowed to develop just as they pleased without the help, control or guidance of government.

It is perhaps only during the last quarter of a century that the contrast between the state of advancement of the medical profession and medical organization on the one hand, and the profession of pharmacy and the drug trade on the other, has become so marked in this country, and perhaps only during the last fifteen years—a period during which the drug trade throughout the world has developed so rapidly and the foundations of an important drug industry in this country have been laid—has the medical profession fully awakened to the grave dangers of the situation and commenced to agitate for some action to be taken by government. Each year for a number of years the Research Workers Conference passed a resolution urging an enquiry on this subject, by this and other means a certain amount of public attention was attracted to it, and eventually in 1930 the Government of India appointed a small committee to go into the whole question. This committee, of which Colonel Chopra was the chairman, visited all parts of India collecting evidence and presented its report in April 1931. The report was a well-reasoned and a comprehensive one; it contained a number of recommendations regarding the organization of the profession of pharmacy and the control of the drug trade and industry.

This report was well received by practically all those whom it concerned (except possibly the dishonest drug trader, and he did not appear in open opposition—as such). The only criticism levelled at it was that some of the measures recommended would cost more money than an impoverished country could at that time afford. But this did not apply to all the recommendations, and it does not seem a sufficient reason for shelving the whole report for a period of over four years—and shelved it must have been as we cannot be expected to believe that it could take four years to mastigate it, even into a completely amorphous state.

During the interval the state of affairs regarding the drug trade has become worse and incidents have occurred that have been quite legitimately described in the public press as 'scandalous'. It has been found that there is a flourishing trade in refilling with useless and possibly deleterious materials the bottles and ampoules bearing the names of well-known and reputable drug manufacturers and reselling them as the genuine article. In a case like this the manufacturers concerned can of course take legal action and get the offenders punished for fraud, but the legal machinery for dealing with even this type of blatant and dangerous dishonesty is cumbersome and the punishment meted out totally inadequate. In the first place, the fraud has to be detected and in the instances referred to it was obvious that it had escaped detection for some considerable time; this sort of thing could never happen in a country where there was any sort of control over the drug trade.

It is of course not only within the country that dishonest practices flourish. Dishonest traders in those European and other countries where there is little control over the export of drugs and medicines have been quick to take advantage of the state of affairs in India and not only import cheap and useless drugs, but have been known to buy up in their own countries condemned stocks of dangerous drugs, such as arsenicals, and time-expired and therefore useless (and possibly dangerous) biological products, and export them to this country.

In the circumstances action by the provincial governments alone would not be effective. It is a matter in which the Federal Government must act in conjunction with the provincial governments. We are not suggesting that an expensive and fully-developed scheme should be thrust upon the country, but a beginning must be made. There are many parts of schemes suggested by Colonel Chopra's committee that would not cost money, and for these the necessary legislation might be proceeded with immediately. It might be suggested that enactment alone would be ineffective but it would produce a moral effect and provide the necessary powers for pushing forward the

scheme immediately money becomes available. The scheme suggested by this committee for organization, registration and training of pharmacists could be carried out at a very small initial expenditure. Again, the existing provincial laboratories could be strengthened without involving the governments in any great capital outlay to carry out the testing of drugs; the addition of only two or three trained men to the existing staffs would probably be all that was necessary to compete with the work for the first few years, and as the work expanded so would the revenue arising therefrom also expand. Although it would obviously be advantageous to have a separate inspecting staff for the collection of samples of drugs in the retail market, this work could be done at first by inspectors of the excise department.

It should be a principle of governments to nurse very carefully the goose that lays the golden eggs. It might even be possible for them to go beyond the moral of the fable and to control their rapacity sufficiently to put aside some of the golden eggs for instituting a golden-egg-laying goose farm. Or, to return to actualities, as there has been an enormous increase in

the revenue derived from the duty on imported drugs during the last fifteen years, it is reasonable that some of this excess should be devoted to establishing laboratories at the principal ports for the testing and control of ordinary drugs, both those imported and those made locally, and a central consultative laboratory for dealing with the more complicated therapeutic agents. Nothing would help the drug industry in this country more than the establishment of efficient control of the manufacture and sale of drugs, and in time this indigenous industry would be in a position to support the whole organization for collecting samples and testing drugs made within the country, as it is only right that it should, just as some at least of the revenue from imported drugs should be devoted to their control.

We feel that the time has now come when medical progress as a whole in the country is being held up by this lack of organization of the profession of pharmacy and lack of control of the drug trade, and we sincerely hope that it will be possible for the government to make some definite move in the matter at an early date.

THE TREND OF IMMUNITY STUDIES IN MALARIA

By R. N. CHOPRA, C.I.E., K.H.P., M.A., M.D. (Cantab.)
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Officiating Director, Calcutta School of Tropical Medicine

and

S. N. MUKHERJEE, M.Sc.

THE problem of immunity in malaria has been the subject of universal attention in view of the fact that the disease has become a standing problem in different important localities of the world where it takes a heavy toll of human lives year after year. In India, which is one of the countries that suffer most, both preventive and curative measures have been subjects of interest with a view to eradicating the evil.

Studies on the problem of immunity really began in 1901 when Daniels made certain observations regarding the tolerance acquired by Europeans and natives residing in the hyperendemic areas of Central Africa. He also pointed out the difference in the nature of immunity acquired by these two races. The work of Christophers (1924) in India also corroborates the observations of Daniels. The period of immunization for Indians residing in the hyperendemic areas was divided by Christophers into three different parts, each characterized by different degrees of splenic

enlargement. After the end of the immunization period, which according to both the above workers covered almost 15 years of life in childhood, the man becomes immune with a latent infection with scanty parasites in the blood. The work of Sarkar (1932) in the Chittagong Hill tracts and also in the tea gardens of Jalpaiguri Duars corroborates the above observation. Gill (1914) further drew attention to the fact that an interruption in infection destroys the immunity and brings about severe epidemics of malaria. This is very interesting from the Indian point of view, specially for those places where malaria is seasonal.

In addition to these epidemiological studies on immunity in malaria, experimental studies on human malaria by different workers, such as Yorke and Macfie (1924), Nicole and Steel (1925), and James (1931), have also brought out many interesting facts. From their observations it is now evident that man varies in his natural resistance to infection and proves refractory to inoculation. A man can develop immunity after an attack of malaria followed by spontaneous recovery from clinical manifestations, but he may still retain some parasites for months. Experimental work on bird and monkey malaria by Gringrich (1932), the Taliaferros (1928), Sinton and Mulligan (1932), Krishnan (1933) and others, also supply information of great importance. Thus, it is

shown that in these malarial cases an immunity is developed which is generally found to be associated with a latent infection and which lasts for a fairly long time. Krishnan *et al.* (1933a and 1934) in their exhaustive work took splenectomy as a means of detecting latent infection. They showed that in monkeys of the susceptible type immunity in a large percentage of cases is associated with a latent infection lasting for about a year and a half after recovery from the acute primary attack, while in a small percentage no latency could be demonstrated. In the resistant species, however, it was found that in a fairly large percentage of cases with acquired immunity, no latent infection could be observed. In birds on the other hand, when the latent infection is totally cured, the immunity disappears.

Investigation into the mechanism of such an immunity as is commonly observed in malaria really began in 1913 with Ziemann's work. Earlier investigators were all unanimous in their conception of protozoal immunity which they believed to be alike in nature to the immunity in bacterial infections. But unfortunately all the attempts made by different workers, Ziemann, Thomson (1918), Kingsbury (1927), and the Taliaferros and Fisher (1927), to demonstrate the presence of an antibody in the blood of human malarial cases by the complement fixation test or by the precipitin test were of no practical value. A few workers, such as Henry (1928), claimed to have diagnosed malaria in human subjects serologically, while Sotiriades and Kauders produced some evidence to show that serum from persons with chronic infection was useful in curing malaria in newly-infected cases. But in spite of all these even Thomson (1933), who is a staunch believer in the existence of an antibody in malaria, has been forced to state that the investigations carried out in this direction are, after all, preliminary and inconclusive; moreover, they are in some cases extremely misleading. Of course, Thomson is of opinion that the obstacle met with in work of such nature is mainly due to the difficulty of obtaining an antigen free from non-specific protein bodies.

The search for an antibody in bird malaria by Taliaferro met with little success. He also observed that serum from birds with latent infection was without action in preventing malaria in normal birds. This failure led Cannon and Taliaferro (1931) to investigate into the cellular reaction in infection and immunity; here they observed some interesting facts. They found that the malarial parasites in birds were phagocytosed at all stages of their development in acute primary infections. They also found evidence of a distinct activation of the mesenchyme which reached its maximum at the time of crisis during which the parasites disappear rapidly from the blood. This activity was found to be equally retained even in the

latent stage. From this it is evident that the mechanism of immunity in birds is cellular and consists of an increased rate of phagocytosis by the reticulo-endothelial system, specially of the spleen and liver. They, however, still believed that some kind of antibody not demonstrable by the ordinary technique was formed, or that the macrophages acquired some specific activity stimulated by some opsonic antibody. In the case of monkey malaria, Taliaferro also came to similar conclusions regarding the presence of an opsonic antibody. Sinton and Mulligan in the course of their extensive researches on monkey malaria tried to demonstrate the presence of antibodies by intradermal reactions, following the injection of antigens of autolysed parasites into monkeys. Although the characteristic reactions appeared in this case as in the case of bacterial autolysates, it did not, however, prove the existence of antibodies, since the consensus of opinion is that there is very little correlation between the occurrence of this reaction and the presence of demonstrable antibodies. But Sinton and Mulligan are of opinion that such delayed intradermal reactions are mainly intracellular rather than humoral, and are consequent upon a reaction between the antigen and an intracellular antibody in the reticulo-endothelial system. Although there might be some hypersensitiveness of the reticulo-endothelial system due to the products of disintegration of other proteins, it was comparatively slight. The major part was due to the specific products derived from the plasmodia used. According to these workers therefore the antibody is not humoral but cellular.

From these observations it seems clear that in the malaria of birds and monkeys the activity of the reticulo-endothelial cells in removing parasites by phagocytosis is a very important factor in the control of the disease. In human malaria the phenomenon of phagocytosis was observed by Golgi as early as 1888, specially in benign tertian and quartan cases. Marchiafava and Bignami in 1894 noted that in malignant tertian malaria the leucocytes were engulfing not only parasite and cell debris, but also the parasites and even the parasitized red cells, and thus removing them from the blood. This observation is very important since it removed an age-long misunderstanding that phagocytes remove only the debris and dead matter and have got nothing to do with the removal of living parasites or red cells. Recent observations have, however, confirmed the observations of Marchiafava and Bignami, not only in the case of malignant tertian malaria but also in benign tertian and quartan cases. With the development of a supra-vital staining technique (*vide* Napier, Krishnan and Lall, 1932) matters have been made easier. It must also be noted in this connection that, while Golgi was of opinion that phagocytosis is a controlling factor in benign tertian and quartan cases, Marchiafava

and Bignami were unable to admit that phagocytosis can completely control the disease in malignant tertian malaria.

From these observations there can be no doubt regarding the importance of phagocytosis as a means of controlling malarial infection. The reticulo-endothelial system of the spleen and the liver shows active phagocytosis of the parasites and the pigment. The activity of the macrophages is seen to a lesser extent in the bone marrow and other organs of the body. This active engulfing of the pigmented parasites may be seen in the peripheral blood stream also where both the macrophages and microphages (mononuclears and neutrophile polymorphonuclears, respectively) are actively phagocytic. So far as is known lymphocytes and eosinophiles are not concerned with the destruction of either parasites or pigment. It is also stated that the endothelial cells at the lining of blood vessels, for example those of the brain, ingest parasites and pigment, but this has not been determined with certainty. The work of Krishnan *et al.* (1933) with a supra-vital staining technique has produced evidence to show that in the process of phagocytosis in malaria the monocytes and the histiocytes are the principal cells that are stimulated.

Since the macrophages have been found to phagocytose both malarial parasites and parasitized red cells, the main problem of malarial immunity now rests upon the point as to how this phagocytosis takes place. The phenomenon, as it occurs in malaria, has been found by Krishnan to be attended with a stimulation of the reticulo-endothelial system as observed by its mobilization and proliferation and also in increased functional activation that consists in the approach of these macrophages toward parasites and infected red cells and the final ingestion of the latter by the former. A knowledge of the mechanism controlling these three processes can alone solve the problem of phagocytosis and it is only after an insight into these processes has been acquired that any possibility of artificially inducing immunity in malaria in man can come up for consideration.

In order that phagocytosis may take place a phagocyte and a parasite or an infected red cell must approach sufficiently close to each other. It is, however, known that leucocytes, parasites and red cells are all negatively charged. Hence an approach of one towards the other always takes place against an electrical force of repulsion to overcome which some work must be done.

In the case of bacterial infections Reeshold was the first to demonstrate that the negative charge of bacteria when they were sensitized was reduced. This has been confirmed by Shibley in 1924. The fact, that bacteria on sensitization by an immune serum become liable to agglutination and phagocytosis, suggests that

both agglutination and phagocytosis are facilitated by a reduction in the electric charge on bacteria, owing to which the work done against electrical repulsion is diminished and the bacteria can come near each other or near the phagocytes and coalesce. Thus it is evident that both the processes of agglutination and phagocytosis resemble the coagulation of colloids where charged particles, on the reduction of their electric charge, approach near each other and conglomerate.

Northrop and Freund (1924) showed that the potential of the red corpuscles sensitized with specific immune serum in a bacterial infection was also reduced. This reduction took place to a degree depending upon the valency of the electrolyte present. Brown and Broom (1929) showed that, on sensitization in a bacterial infection, the charge of both red blood cells and bacteria present in the blood is reduced in proportion to the strength of the immune serum used.

Brown (1933), at the suggestion of Findlay, extended his work on charge measurement to red blood cells in malarial cases, to see whether the electrical charge on red cells suffered any reduction due to malarial infection, as happens in the case of bacterial infection.

The idea underlying such a piece of work was that if any reduction in the electrical charge of red blood cells in malarial infection, as compared to that in normal subjects, could be found, then from the analogy of the association of the antibody formation with charge reduction, as demonstrated in bacterial infections, this finding might support the theory of antibody formation in malaria.

The extensive work of Brown (1933a) did in actual fact show that the electric charge on red cells in malaria was reduced as compared to that in normal subjects, and that the reduction of charge was progressive and proportionate to the parasite rate. Brown and Broom (1935) also produced evidence to show that the reduction in electrical charge promoted phagocytosis and that any interference with the reduction interfered with the phagocytosis as well. Regarding the influence of serum in malarial immunity he showed that serum from a bird with latent infection reduced the charge on red blood cells from a normal bird, but that this action on the part of the serum was purely non-specific since reduction in charge could also be observed in the case of red cells from the blood of any other species of animal and even in the case of bacteria. This non-specificity does not however give any definite indication regarding the formation of specific antibodies. He, however, attacked the problem from a different point of view. With the infection of *Trypanosoma equiperdum* he showed that the reduction of the electrical charge of red cells occurred not when the infection was acute but when a treatment of Bayer

205 was given. The time and the condition of the charge reduction however coincided with those of the appearance of antibodies in the blood. This association of charge reduction with the appearance of antibodies in the blood, in all probability, indicated that the mechanism of charge reduction in malaria was similar to that in the present case and that some specific antibodies might possibly be formed in malarial cases also. From a serological point of view he tried to establish the same thing. Ledingham (1907) showed that immunity in diphtheria in horses is associated with an increase in the globulin portion of the blood serum. Similar association of antibodies has been observed by different workers in different bacterial infections. In malaria also this globulin fraction has been observed to increase both by Lloyd and Paul (1928) and by Chopra, Mukherjee and Sen (1935). Brown noted a great charge-reducing action of the globulins of blood sera. This increase in the globulin fraction as well as a consequent diminution of electric charge pointed to the possibility of antibody being formed in this case also. Moreover, the fact that the malarial immunity, as observed, is of a specific nature, since an immunity acquired against one strain cannot prevent infection with another, again points to the possibility of the formation of a specific antibody in this case also.

Findlay and Brown (1934) in a recent paper have produced evidence to show that serum from a bird with latent infection can sensitize the infected cells in another bird provided that such infected cells are small in number; also that blood from a canary which is recovering from an acute attack produces infection less readily than the blood from the same canary at the beginning of the attack, the number of infected cells being the same in each case. In spite of these observations and of evidence from analogy to prove the existence of an antibody in the blood, Findlay and Brown have not been able to explain the non-specific action of serum in such cases. In fact they have admitted that the action of serum is both specific and non-specific. The specific action occurs only when the phagocytosis of the parasites takes place during their extra-cellular existence. This is very suggestive, since such is the case in bacterial infection, as bacteria usually remain in the circulation and the phagocytosis of bacteria is due to the specific action of serum. The non-specific action consists in the activation of the reticulo-endothelial system and also in serological changes in the blood.

To sum up, therefore, the present position of immunity, it may safely be said that our whole conception of the mechanism centres round the possibility of the formation of an antibody. Although the existence of such specific antibodies have not been directly demonstrated, indirect evidence from an analogy of the physical and serological behaviour of blood in both

malarial and bacterial infections have been brought forward in support of this view. The mechanism of phagocytosis is accordingly believed to be due to a reduction of electrical charge on red cells. Both red cells and white cells being negatively charged, ordinarily the forces of electrical repulsion prevent a white cell from coming near a red cell, but when this red cell is infected its electrical charge is diminished and in consequence the approach of the two near each other becomes a possibility as a result of the reduced forces of repulsion.

The work of Chopra and Chaudhury (1933) on Indian strains of malaria in human subjects showed that the variation of electrical charge was not as regular as Brown observed in cases of bird malaria. The electrical charge varies in all possible ways. In some instances an increase above the average normal value was observed, while in others both equality and reduction were found. These observations, however, evidently indicated that the mechanism by means of which phagocytosis of red cells were brought about was not as simple as Brown suggested. Over and above this it threw some doubt on the existence, in such cases, of an antibody that brings about a lowering of the electric charge of red blood cells, because the charge was not found to be lowered in all cases.

Quite recently Chopra, Mukherjee and Krishnan (1935) took up this problem again to examine what would be the factors responsible for such irregular variation in electric charge on red cells and how far the electric charge would go to explain the facts about phagocytosis observed herein. The work was carried out on monkeys heavily infected with *Plasmodium knowlesi*, nearly 70 per cent of the red cells being infected. As observed from a measurement of the migration velocity of red cells in an electric field, it was observed that there was a fundamental difference between the healthy and the infected red cells of an infected blood specimen. The charge on the infected cells in general was lower than that on the healthy cells. This observation was very interesting since none of the previous workers could detect any difference between the electrical charges of infected and uninfected red cells. The next point observed was that the charge on the infected cells was dependent upon the stage of the parasites' growth within the cell. In the ring stage, infected cells showed a charge slightly higher than normal, while in the fully-mature schizont stage the charge was much lower. These observations directly give a clue to the peculiar and irregular variation of electrical charge as observed by Chopra and Chaudhury (*loc. cit.*). They also indicate that since electrical charge controls the approach of a phagocyte to a red cell, red cells with the fully-mature schizont stage of parasite within them are more liable to be phagocytosed. The inferences arrived at are, therefore, interesting and have practical

and Bignami were unable to admit that phagocytosis can completely control the disease in malignant tertian malaria.

From these observations there can be no doubt regarding the importance of phagocytosis as a means of controlling malarial infection. The reticulo-endothelial system of the spleen and the liver shows active phagocytosis of the parasites and the pigment. The activity of the macrophages is seen to a lesser extent in the bone marrow and other organs of the body. This active engulfing of the pigmented parasites may be seen in the peripheral blood stream also where both the macrophages and microphages (mononuclears and neutrophile polymorphonuclears, respectively) are actively phagocytic. So far as is known lymphocytes and eosinophiles are not concerned with the destruction of either parasites or pigment. It is also stated that the endothelial cells at the lining of blood vessels, for example those of the brain, ingest parasites and pigment, but this has not been determined with certainty. The work of Krishnan *et al.* (1933) with a supra-vital staining technique has produced evidence to show that in the process of phagocytosis in malaria the monocytes and the histiocytes are the principal cells that are stimulated.

Since the macrophages have been found to phagocytose both malarial parasites and parasitized red cells, the main problem of malarial immunity now rests upon the point as to how this phagocytosis takes place. The phenomenon, as it occurs in malaria, has been found by Krishnan to be attended with a stimulation of the reticulo-endothelial system as observed by its mobilization and proliferation and also an increased functional activation that consists in the approach of these macrophages towards parasites and infected red cells and the final ingestion of the latter by the former. A knowledge of the mechanism controlling these three processes can alone solve the problem of phagocytosis and it is only after an insight into these processes has been acquired that any possibility of artificially inducing immunity in malaria in man can come up for consideration.

In order that phagocytosis may take place a phagocyte and a parasite or an infected red cell must approach sufficiently close to each other. It is, however, known that leucocytes, parasites and red cells are all negatively charged. Hence an approach of one towards the other always takes place against an electrical force of repulsion to overcome which some work must be done.

In the case of bacterial infections Bechold was the first to demonstrate that the negative charge of bacteria when they were sensitized was reduced. This has been confirmed by Shibley in 1924. The fact, that bacteria on sensitization by an immune serum become liable to agglutination and phagocytosis, suggests that

both agglutination and phagocytosis are facilitated by a reduction in the electric charge on bacteria, owing to which the work done against electrical repulsion is diminished and the bacteria can come near each other or near the phagocytes and coalesce. Thus it is evident that both the processes of agglutination and phagocytosis resemble the coagulation of colloids where charged particles, on the reduction of their electric charge, approach near each other and conglomerate.

Northrop and Freund (1924) showed that the potential of the red corpuscles sensitized with specific immune serum in a bacterial infection was also reduced. This reduction took place to a degree depending upon the valency of the electrolyte present. Brown and Broom (1929) showed that, on sensitization in a bacterial infection, the charge of both red blood cells and bacteria present in the blood is reduced in proportion to the strength of the immune serum used.

Brown (1933), at the suggestion of Findlay, extended his work on charge measurement to red blood cells in malarial cases, to see whether the electrical charge on red cells suffered any reduction due to malarial infection, as happens in the case of bacterial infection.

The idea underlying such a piece of work was that if any reduction in the electrical charge of red blood cells in malarial infection, as compared to that in normal subjects, could be found, then from the analogy of the association of the antibody formation with charge reduction, as demonstrated in bacterial infections, this finding might support the theory of antibody formation in malaria.

The extensive work of Brown (1933a) did in actual fact show that the electric charge on red cells in malaria was reduced as compared to that in normal subjects, and that the reduction of charge was progressive and proportionate to the parasite rate. Brown and Broom (1935) also produced evidence to show that the reduction in electrical charge promoted phagocytosis and that any interference with the reduction interfered with the phagocytosis as well. Regarding the influence of serum in malarial immunity he showed that serum from a bird with latent infection reduced the charge on red blood cells from a normal bird, but that this action on the part of the serum was purely non-specific since reduction in charge could also be observed in the case of red cells from the blood of any other species of animal and even in the case of bacteria. This non-specificity does not however give any definite indication regarding the formation of specific antibodies. He, however, attacked the problem from a different point of view. With the infection of *Trypanosoma equiperdum* he showed that the reduction of the electrical charge of red cells occurred not when the infection was acute but when a treatment of Bayer

205 was given. The time and the condition of the charge reduction however coincided with those of the appearance of antibodies in the blood. This association of charge reduction with the appearance of antibodies in the blood, in all probability, indicated that the mechanism of charge reduction in malaria was similar to that in the present case and that some specific antibodies might possibly be formed in malarial cases also. From a serological point of view he tried to establish the same thing. Ledingham (1907) showed that immunity in diphtheria in horses is associated with an increase in the globulin portion of the blood serum. Similar association of antibodies has been observed by different workers in different bacterial infections. In malaria also this globulin fraction has been observed to increase both by Lloyd and Paul (1928) and by Chopra, Mukherjee and Sen (1935). Brown noted a great charge-reducing action of the globulins of blood sera. This increase in the globulin fraction as well as a consequent diminution of electric charge pointed to the possibility of antibody being formed in this case also. Moreover, the fact that the malarial immunity, as observed, is of a specific nature, since an immunity acquired against one strain cannot prevent infection with another, again points to the possibility of the formation of a specific antibody in this case also.

Findlay and Brown (1934) in a recent paper have produced evidence to show that serum from a bird with latent infection can sensitize the infected cells in another bird provided that such infected cells are small in number; also that blood from a canary which is recovering from an acute attack produces infection less readily than the blood from the same canary at the beginning of the attack, the number of infected cells being the same in each case. In spite of these observations and of evidence from analogy to prove the existence of an antibody in the blood, Findlay and Brown have not been able to explain the non-specific action of serum in such cases. In fact they have admitted that the action of serum is both specific and non-specific. The specific action occurs only when the phagocytosis of the parasites takes place during their extra-cellular existence. This is very suggestive, since such is the case in bacterial infection, as bacteria usually remain in the circulation and the phagocytosis of bacteria is due to the specific action of serum. The non-specific action consists in the activation of the reticulo-endothelial system and also in serological changes in the blood.

To sum up, therefore, the present position of immunity, it may safely be said that our whole conception of the mechanism centres round the possibility of the formation of an antibody. Although the existence of such specific antibodies have not been directly demonstrated, indirect evidence from an analogy of the physical and serological behaviour of blood in both

malarial and bacterial infections have been brought forward in support of this view. The mechanism of phagocytosis is accordingly believed to be due to a reduction of electrical charge on red cells. Both red cells and white cells being negatively charged, ordinarily the forces of electrical repulsion prevent a white cell from coming near a red cell, but when this red cell is infected its electrical charge is diminished and in consequence the approach of the two near each other becomes a possibility as a result of the reduced forces of repulsion.

The work of Chopra and Chaudhury (1933) on Indian strains of malaria in human subjects showed that the variation of electrical charge was not as regular as Brown observed in cases of bird malaria. The electrical charge varies in all possible ways. In some instances an increase above the average normal value was observed, while in others both equality and reduction were found. These observations, however, evidently indicated that the mechanism by means of which phagocytosis of red cells were brought about was not as simple as Brown suggested. Over and above this it threw some doubt on the existence, in such cases, of an antibody that brings about a lowering of the electric charge of red blood cells, because the charge was not found to be lowered in all cases.

Quite recently Chopra, Mukherjee and Krishnan (1935) took up this problem again to examine what would be the factors responsible for such irregular variation in electric charge on red cells and how far the electric charge would go to explain the facts about phagocytosis observed herein. The work was carried out on monkeys heavily infected with *Plasmodium knowlesi*, nearly 70 per cent of the red cells being infected. As observed from a measurement of the migration velocity of red cells in an electric field, it was observed that there was a fundamental difference between the healthy and the infected red cells of an infected blood specimen. The charge on the infected cells in general was lower than that on the healthy cells. This observation was very interesting since none of the previous workers could detect any difference between the electrical charges of infected and uninfected red cells. The next point observed was that the charge on the infected cells was dependent upon the stage of the parasites' growth within the cell. In the ring stage, infected cells showed a charge slightly higher than normal, while in the fully-mature schizont stage the charge was much lower. These observations directly give a clue to the peculiar and irregular variation of electrical charge as observed by Chopra and Chaudhury (*loc. cit.*). They also indicate that since electrical charge controls the approach of a phagocyte to a red cell, red cells with the fully-mature schizont stage of parasite within them are more liable to be phagocytosed. The inferences arrived at are, therefore, interesting and have practical

significance. An explanation as to why the charge of a red cell, with fully-mature schizonts in it, is less than normal seems to be obvious when we consider the fact that the parasite within the cell lives and grows at the expense of the latter, as a result of which the chemical composition of the entire cell, including both the interior and the exterior, undergoes a change. The deterioration of the surface probably brings about an alteration in the electrical charge. A small increase of charge when the parasite enters the cell and is in the ring form is also not difficult to understand, because as soon as a parasite comes in contact with a red cell the common surface of contact cannot have any charge, which distributes itself on the total free surface. Hence owing to the distribution of the same charge on a smaller surface the total charge of the cell increases. The third point observed in this connection is that reticulocytes have got the same charge as the adult cells and hence, from an electrical point of view, there is no reason why reticulocytes should not be infected with parasites as is the case with adult red cells. In one blood specimen, infected reticulocytes were actually observed (Krishnan, Chopra and Mukherjee, 1935). The relative freedom of these may be understood on the basis of a simple consideration of the mathematics of probability, inasmuch as the number of reticulocytes in blood being very small, the chances of their meeting parasites during the short extra-cellular existence of the latter are ordinarily very small.

The considerations based upon the knowledge of the electrical charge of red cells are, therefore, very helpful in understanding some of the behaviour observed in malarial blood. When these considerations of electric charge are further extended to the understanding of the mechanism of phagocytosis, the subject becomes still more interesting. The relationship between the electrical charge of red blood cells and the phagocytosis thereof is governed by the laws of collision between charged particles as in colloids. The mathematical expression as deduced from the above considerations require the knowledge of the electrical charge of white cells and the di-electric nature of the plasma. It is a known fact that, where repulsive forces due to electrical charge come in, the charges on both the particles acted on by such forces should be taken into consideration. The di-electric nature of the medium (here plasma) which separates these two charged bodies should also be taken into account since it is a well-known fact that besides the electrical charge of the repelling particles the nature of the medium also determines the actual magnitude of electrical force between the cells. From the mathematical expression again, it has been shown in the paper mentioned above that a small change in the medium may bring about a considerable alteration in the magnitudes of the electrical

forces. It is, therefore, evident that, so far as phagocytosis is concerned, the consideration of the electrical charge on the red cells is not enough. The charge on the white cells and the alterations in the plasma are also important and according to the recent work in this laboratory it appears that the changes in the plasma are perhaps more important than the electrical charges on the individual cells (Krishnan, 1936).

It is, however, known that some of the constituents of blood plasma undergo changes in the course of malarial infection. Thus euglobulin has been observed to increase, albumin to decrease and cholesterol also to decrease. Such changes obviously produce alterations in the magnitude of the force of electrical repulsion, which is a determining factor in bringing the charged particles close together and thereby in phagocytosis. In the absence of any definite proof as to the existence of an antibody in the blood and also in view of the fact that the variation of electrical charge is not as regular in all cases as shown by Brown, the quota contributed by the biochemical alterations in the blood in the explanation of such facts seems to be full of possibilities.

Further work in this direction is in progress to assess the rôle of biochemical changes in the plasma, and, if it is found that biochemical alterations are as important as is indicated by the mathematical expression deduced for phagocytosis, the question of artificially inducing such alterations in the blood may come up for consideration for the purpose of promoting immunity against this disease.

MEDICAL RESEARCH IN INDIA*

By G. G. JOLLY, C.I.E., V.H.S.

LIEUTENANT-COLONEL, I.M.S.

• Officiating Public Health Commissioner with the Government of India, New Delhi

THE present occasion when the 13th Conference of Medical Research Workers in India is meeting here in Calcutta is a suitable opportunity to invite your attention for a few minutes to the subject of Medical Research in its relation to Health. My first remarks will be historical to bring you up to date with the present position in India.

Less than seventy years ago the Government of India appointed two medical men, Drs. Lewis and Cunningham, as special assistants to the sanitary commissioner with the Government of India, for the purpose of utilizing scientific investigations for the benefit of public health. The great need at that time was the initiation of scientific investigation into disease problems particularly with the aid of the then new but rapidly developing methods of bacteriology. Both these officers were research workers and both achieved distinction as such. Lewis was a pioneer in parasitology who made important discoveries in connection with the parasite cause of elephantiasis and the group of blood parasites known as the trypanosomes, members of which cause sleeping sickness in man and 'surra' in horses. Cunningham, ten years after his appointment under the Sanitary Commissioner, was given the chair of physiology in this town and held it for 18 years during which he managed a small laboratory, the only one of its kind in India.

The date 1869 then marks the beginning of a period of active development of medical research in India. In the decades that followed, progress has been rapid and laboratories and institutions for research have been built in many parts of India.

In 1896 on the introduction of plague at Bombay the bacteriologist, Haffkine, transferred from Bengal, where he had been engaged on anti-cholera inoculation work, opened in temporary quarters his first plague laboratory which after various moves was finally located on a larger scale in old Government House, Parel, where the Haffkine Institute remains as his memorial and still produces for India the plague vaccine which he first created.

* Being an address read at the Rotary Club, Calcutta, on the 3rd December, 1935.

significance. An explanation as to why the charge of a red cell, with fully-mature schizonts in it, is less than normal seems to be obvious when we consider the fact that the parasite within the cell lives and grows at the expense of the latter, as a result of which the chemical composition of the entire cell, including both the interior and the exterior, undergoes a change. The deterioration of the surface probably brings about an alteration in the electrical charge. A small increase of charge when the parasite enters the cell and is in the ring form is also not difficult to understand, because as soon as a parasite comes in contact with a red cell the common surface of contact cannot have any charge, which distributes itself on the total free surface. Hence owing to the distribution of the same charge on a smaller surface the total charge of the cell increases. The third point observed in this connection is that reticulocytes have got the same charge as the adult cells and hence, from an electrical point of view, there is no reason why reticulocytes should not be infected with parasites as is the case with adult red cells. In one blood specimen, infected reticulocytes were actually observed (Krishnan, Chopra and Mukherjee, 1935). The relative freedom of these may be understood on the basis of a simple consideration of the mathematics of probability, inasmuch as the number of reticulocytes in blood being very small, the chances of their meeting parasites during the short extra-cellular existence of the latter are ordinarily very small.

The considerations based upon the knowledge of the electrical charge of red cells are, therefore, very helpful in understanding some of the behaviour observed in malarial blood. When these considerations of electric charge are further extended to the understanding of the mechanism of phagocytosis, the subject becomes still more interesting. The relationship between the electrical charge of red blood cells and the phagocytosis thereof is governed by the laws of collision between charged particles as in colloids. The mathematical expression as deduced from the above considerations require the knowledge of the electrical charge of white cells and the di-electric nature of the plasma. It is a known fact that, where repulsive forces due to electrical charge come in, the charges on both the particles acted on by such forces should be taken into consideration. The di-electric nature of the medium (here plasma) which separates these two charged bodies should also be taken into account since it is a well-known fact that besides the electrical charge of the repelling particles the nature of the medium also determines the actual magnitude of electrical force between the cells. From the mathematical expression again, it has been shown in the paper mentioned above that a small change in the medium may bring about a considerable alteration in the magnitudes of the electrical

forces. It is, therefore, evident that phagocytosis is concerned, the consideration of the electrical charge on the red cell is not enough. The charge on the white cells and alterations in the plasma are also important. According to the recent work in this connection it appears that the changes in the plasma are perhaps more important than the changes in the charges on the individual cells (Krishnan).

It is, however, known that some constituents of blood plasma undergo alterations in the course of malarial infection. Euglobulin has been observed to decrease and cholesterol to increase. Such changes obviously alter the magnitude of the electrical repulsion, which is a determining factor in bringing the charged particles together and thereby in phagocytosis. In the absence of any definite proof as to the role of an antibody in the blood and also of the fact that the variation of electrical charge is not as regular in all cases as in Brown, the quota contributed by the blood alterations in the blood in the explanation of such facts seems to be full of possibilities.

Further work in this direction is in progress to assess the rôle of biochemical changes in plasma, and, if it is found that biochemical alterations are as important as is indicated by the mathematical expression deduced from phagocytosis, the question of artificially inducing alterations in the blood may come up for consideration for the purpose of promoting immunity against this disease.

MEDICAL RESEARCH IN INDIA*

By G. G. JOLLY, C.I.E., V.H.S.

LIEUTENANT-COLONEL, I.M.S.

• Officiating Public Health Commissioner with the Government of India, New Delhi

THE present occasion when the 13th Conference of Medical Research Workers in India is meeting here in Calcutta is a suitable opportunity to invite your attention for a few minutes to the subject of Medical Research in its relation to Health. My first remarks will be historical to bring you up to date with the present position in India.

Less than seventy years ago the Government of India appointed two medical men, Drs. Lewis and Cunningham, as special assistants to the sanitary commissioner with the Government of India, for the purpose of utilizing scientific investigations for the benefit of public health. The great need at that time was the initiation of scientific investigation into disease problems particularly with the aid of the then new but rapidly developing methods of bacteriology. Both these officers were research workers and both achieved distinction as such. Lewis was a pioneer in parasitology who made important discoveries in connection with the parasite cause of elephantiasis and the group of blood parasites known as the trypanosomes, members of which cause sleeping sickness in man and 'surra' in horses. Cunningham, ten years after his appointment under the Sanitary Commissioner, was given the chair of physiology in this town and held it for 18 years during which he managed a small laboratory, the only one of its kind in India.

The date 1869 then marks the beginning of a period of active development of medical research in India. In the decades that followed, progress has been rapid and laboratories and institutions for research have been built in many parts of India.

In 1896 on the introduction of plague at Bombay the bacteriologist, Haffkine, transferred from Bengal, where he had been engaged on anti-cholera inoculation work, opened in temporary quarters his first plague laboratory which after various moves was finally located on a larger scale in old Government House, Parel, where the Haffkine Institute remains as his memorial and still produces for India the plague vaccine which he first created.

* Being an address read at the Rotary Club, Calcutta, on the 3rd December, 1935.

The Pasteur Institute of India was founded at Kasauli in 1900, a similar institute at Coonoor in 1903. The King Institute of Preventive Medicine at Guindy, Madras, was opened in 1904 and the Central Research Institute, Kasauli, in 1906.

In 1916 Burma opened its Pasteur Institute in Rangoon and Assam followed with a similar one at Shillong in 1917.

The opening of the Calcutta School of Tropical Medicine in 1920 and the notable part played in its foundation by two illustrious Calcutta doctors, Pardey Lukis and Leonard Rogers, will be recalled by some here to-day, while most of you will remember well its distinguished first Director, Sir John Megaw, who like Sir Leonard Rogers still takes the deepest interest in its fortunes. Last, I must mention the All-India Institute of Hygiene and Public Health, like the Tropical School a combined teaching and research institute, but whose foundation we owe to a trust which has probably done more for human welfare throughout the world than any similar body—the Rockefeller Foundation.

I come now to two events of much importance to the organization of medical research in India. The first was the creation in 1906 of a bacteriological department under the Government of India. Not all research workers came into this department, but the officers employed in the various Government laboratories throughout India, in which medical research was carried out, were linked together in a cadre and given improved conditions. With minor modifications this bacteriological department persists though its name has been changed to 'medical research department' and from it the various Government research laboratories whether central or provincial are staffed.

The second important event was the constitution in 1911 of an organization for research known as the 'Indian Research Fund Association' and it is interesting to note that its creation preceded that of the Medical Research Council in England which only came into being during the Great War. The formation of the Indian Research Fund Association was largely due to the vision and administrative ability of a distinguished servant of India, Sir Harcourt Butler. Its original objects were the encouragement of medical research by financing approved enquiries and the supply of suitable research workers. The rules of the association do not restrict us to any special lines of medical research except that it is laid down that research into communicable disease should specially be carried out and in practice the funds of the association have been largely devoted to investigations into the major endemic and epidemic diseases of India.

For finance the association depended upon an annual Government grant of five lakhs of rupees. Its control is by a representative governing body which has the Government of

India Member of Education, Health and Lands as its chairman. Technical advice on the many aspects of medical research is supplied by a scientific advisory board of experts under the chairmanship of the Director-General, Indian Medical Service, while the Public Health Commissioner with the Government of India is honorary secretary both to the governing body and to the scientific advisory board.

The association has its own publication—the *Indian Journal of Medical Research*—which has won for itself a high international reputation. It also issues 'memoirs' on special subjects from time to time.

While the bacteriological department, or as it is now called the medical research department, is a cadre of Government officers, the Indian Research Fund Association is not restricted to such officers in its choice of research workers and in fact employs a large number of private workers in its various enquiries.

During the 65 years that have elapsed since the appointment of Drs. Lewis and Cunningham, a vast amount of medical research has been carried out, ranging over practically every disease that is of importance in this country. Malaria, plague, rabies, relapsing fever, typhus fever in which investigation we lost a distinguished research worker—Major Cragg, cholera, typhoid, dysentery, leprosy, kala-azar, beri-beri, sprue, oriental sore; these and many other diseases have been investigated and have yielded up many of their secrets.

In some cases a great discovery has been made by a lone worker and we have Ronald Ross's mingled feelings of wonder and awe when 37 years ago he discovered here in Calcutta the mosquito transmission of malaria, preserved for all time in his lines.

This day relenting God,
Hath placed within my hand,
A wondrous thing; and God
Be praised. At his Command,

Seeking His secret deeds
With tears and toiling breath,
I find thy cunning seeds,
O million-murdering Death.

I know this little thing
A myriad men will save,
O Death, where is thy sting?
Thy Victory, O Grave?

On the other hand, the hidden truth may be reached only after a long series of patient almost meticulous investigations by a team of experts who approach the problem from various aspects, collating their results as they go along and fitting each new fact ascertained into its proper place like the pieces of a jigsaw puzzle. Of such a nature was the work of the Indian Plague Commission which disclosed in marvellous detail the really amazing story of the transmission and spread of plague from rat to

rat and from rat to man through the mediation of the flea.

These introductory remarks lead me to the conference now meeting in the School of Tropical Medicine.

This conference is one of experts—actual workers on medical research problems drawn from all over India—and also medical officers of health. The conference is held with the approval of the Government of India who invite local Governments and administrations to send representatives, while the chairman, who is the Director-General, Indian Medical Service, also invites certain workers who might otherwise be left out. Although held with the approval of the Government of India, the conference is organized by the Indian Research Fund Association for its main object is to provide an opportunity for technical discussion of the research work carried out under the auspices of this association and for its appraisal with a view to the future programmes of works.

The conference exercises no official authority, the views of its members do not necessarily bind the administrations from which they come, while the recommendations it makes and the resolutions it passes represent nothing more than the majority view of the members composing it. Probably in this very vagueness of its relations and its lack of official authority and responsibility lie its greatest value. Its discussions of research work are frank and highly critical and its recommendations and resolutions unfettered by the restrictions necessarily imposed upon delegates bound by official 'instructions'.

The association of research workers and medical officers of health in the conference is no haphazard one. A research worker necessarily concentrates upon the subject he is investigating which is apt in his outlook to assume enhanced importance. This tendency as well as the stringent financial limitation imposed in these days upon medical research in India renders close association and free discussion with officers who have their fingers on the public health pulse highly desirable. Health officers on the other hand, in proportion as they are out of touch with the progress of medical research, are out of date.

Finally the conference provides, once a year, an opportunity for research workers, engaged upon similar or allied enquiries and health officers faced with identical or analogous problems in widely distant parts of India, to meet and pursue for a few days an intensive exchange and comparison of ideas. The value of this annual mental purge and tonic in a sub-continent like India is almost incalculable, and it accrues, be it not forgotten, not merely or in the main to the individual representative sent but principally to the administration employing him.

Attendance at the conference is no 'joy-ride'. There are no 'social functions' in its programme and hard work is the order of the day: indeed the volume of work is too great to be dealt with in full session, hence much is done by committees. At the present conference there are five such committees, which were constituted at a meeting of the scientific advisory board immediately preceding the conference. They deal with malaria, cholera, plague, leprosy and rabies. These committees may vary from year to year according to the amount of work involved. Thus, next year it may be desirable to form a committee on nutrition and deficiency diseases—a subject whose importance to India is coming to be more fully recognized. The nutrition of the people is of fundamental importance in relation to health problems and is closely connected with economic conditions and questions of population and social progress.

It is impossible in the remaining minutes at my disposal to detail the various researches which are now in progress or under contemplation for next year, but I can give you a rough indication of their scope.

Malaria, the most important disease endemic in India, occupies a prominent place in our programme, and investigations into it are organized under the Malaria Survey of India, financed by the Indian Research Fund Association and based on Kasauli. This Survey does a vast amount of investigation including special research work and local surveys. It holds post-graduate classes in malaria for the training of experts and publishes a journal called *Records of the Malaria Survey of India*. Malaria surveys of Sind in relation to irrigation and of Quetta with special reference to post earthquake conditions have recently been completed and some very valuable work has been accomplished at Karachi in connection with the threatened introduction of yellow fever.

Cholera is a disease whose home is India, and the world looks to us for the solution of its problems. An attack on these problems has been organized and many lines of work are being pursued at Kasauli, here in Bengal and in Assam. Much is hoped for from the teamwork now in progress and results so far are encouraging.

In plague, research is being pursued in Bombay into the preparation of a potent anti-plague serum for treatment, and on improvements in the efficacy of the famous preventive vaccine of Haffkine. An important epidemiological enquiry is also in progress in the Cum-bum Valley of Madras Presidency.

Rabies research includes improvement of the vaccines now in use both for men and animals and a statistical analysis of the results of treatment throughout India.

In leprosy, attempts are being made to cultivate outside the body the causative germ of

the disease, while a study of rat leprosy is in progress. Improved methods of treatment are constantly being sought and tried out.

Outside the scope of the special committees we have many enquiries. Under 'Nutrition' we have in progress a systematic survey of Indian foodstuffs and an enquiry on cheap balanced diets, also investigations into the causation of stone in the bladder and into vitamin deficiency; while field observations have been made with the object of obtaining data, of the standard of physique in relation to diet and the incidence of food deficiency diseases.

Investigations proceed into the action of various drugs, indigenous and others, into drug addiction, into typhus fever, snake venoms, epidemic dropsy, cancer, tuberculosis, anaemia of women, worm diseases, fungus diseases, cirrhosis of the liver, cataract and, I am glad to say, that scourge of India, the contagious eye disease 'trachoma'.

I have said enough to indicate the present scope of our activities; what of our finances? Alas they are far from satisfactory. When the financial crisis occurred a few years ago, the Government of India found it necessary to reduce our annual grant from Rs. 7½ lakhs to Rs. 1½ lakhs. Fortunately a considerable sum has accumulated to the credit of the Indian Research Fund Association during the War and Post War years and by drawing on these savings it has been possible to maintain the level of the research work, but these savings are rapidly dwindling and we can only hope that when they are gone it will again be found possible to augment our grant for research. We have spent this year roughly twice our income and have drawn four lakhs from our accumulated funds.

We are perhaps open to the accusation that we have not cut our coat according to our cloth and had better reduce our expenditure and balance our budget, but Gentlemen! it is no light matter to cut down, by one half, the medical research that is going on in India at the present moment. If there is one thing upon which all the public health experts and research workers attending the present conference are unanimous, and unanimity is hard to find among such persons, it is upon the need for more medical research in India and it would take a bold man and perhaps a foolhardy man to say that the resources of Government and of philanthropists in India are exhausted and that medical research must therefore have its activities drastically curtailed.

I have mentioned philanthropists, for medical research in all countries makes the strongest appeal to those who appreciate, what it has already done, for humanity and who have the imagination to visualize its potentialities for the future. Unfortunately with the exception

of a munificent grant from the Raja of Parlakimedi the Indian Research Fund Association has so far had no financial support from any non-Government source. Nevertheless no worthier object for public support could exist. I could dilate upon this point extensively had I time, but will content myself with one example.

Before the introduction of Jenner's vaccination, smallpox was regarded throughout Europe and the East as a necessary evil which only the fortunate few escaped. Now, owing to that vaccination, it has become 'the perquisite of those who elect to have it'.

Two cautions demand mention before I finish. The greatest discoveries of medical research are still-born unless they are acted upon, and here in India there is a tendency for the application of our knowledge to lag behind its attainment. Thus we still get extensive epidemics of the so easily preventable disease smallpox, while in too many of our cities we continue to permit the creation of slums providing just those conditions which investigation has shown to facilitate the spread of tuberculosis of the lungs.

Sixty-five years ago the crying need was for knowledge of the mode of spread of our main diseases such as malaria and plague. To-day we still have a vast amount to learn, but perhaps our greater problem is the successful application of the theoretical knowledge we already possess, and this in itself requires much patient investigation, largely in the field.

The other point I would make is that there is no short cut to health which avoids the costly road of environmental hygiene. If we are to have a healthy people we must face the cost of pure and sufficient water, good drainage and refuse disposal, wholesome unadulterated foods and healthy houses with avoidance of overcrowding. These are essentials which no stunt sanitation can replace and no amount of research can ever enable us to dispense with.

Gentlemen, I do not think it is an exaggeration to say that were it not for medical research less than half of us would be present here to-day. I have been told that formerly European residents of Calcutta used to meet annually to congratulate themselves on having survived another year, and there is no reason to believe that among other sections of the community health conditions were any better. To-day it is possible to obtain a life insurance policy without any additional premium for residence in India.

This is however not the end but the beginning; many diseases still flourish that should be prevented, many others lie in wait for the time when we shall be off our guard. Medical research must always be required, as the intelligence department of an army, constantly mobilized against what Paul Zinsser has called 'these ferocious little fellow creatures which lurk in the dark corners and stalk us in the bodies of

rats, mice and all kinds of domestic animals; which fly and crawl with the insects and way-

lay us in our food and drink and even in our love'.

Medical News

SALVARSAN SILVER JUBILEE

ON 10th December, 1935, a special meeting was held in the auditorium of the All-India Institute of Hygiene and Public Health to celebrate the twenty-fifth anniversary of the first introduction of salvarsan into therapeutics.

The room was well filled and the gathering was a representative one. Dr. A. C. Brocke, D.Sc., opened the proceedings in the following words:—

Ladies and Gentlemen,

On behalf of the Scientific Department of Bayer-Meister Lucius, the organizers of this meeting at which this distinguished gathering of medical men and scientists have come together to celebrate the silver jubilee of the discovery of salvarsan and to do honour to its inventor Paul Ehrlich, I have the great honour to welcome you here to-day.

We have been particularly fortunate in having as our speakers to-day such distinguished scientists as Brevet-Colonel R. N. Chopra, C.I.E., K.H.P., M.A., M.D., M.R.C.P., I.M.S., and Lieutenant-Colonel K. K. Chatterji, F.R.C.S.I., I.T.F. It would be incongruous if I were to introduce either of these speakers as both are already so well known to you all and their research work has gained them a reputation not only in this country but in the medical world at large. I feel that this is a good opportunity for thanking, on behalf of the medical and chemical research workers of our scientific department of which I am the humble representative in Calcutta, not only the two speakers but the many other workers in Calcutta for their co-operation with us in the search for new drugs to use in our fight against disease. The laboratories in Elberfeld and Frankfurt can work out and prepare drugs and test them on animals just as Ehrlich did 25 years ago, but they are dependent on those workers in the field with a scientific outlook to give the necessary clinical trials under carefully-controlled conditions before they can issue them for use to the general medical profession.

The disease which Paul Ehrlich was fighting is an universal one and therefore he could carry out the initial trials in our own country. However to continue his research it was necessary to look to workers in this country for guidance in certain aspects, such as in the suitable dosage to be recommended to doctors whose patients are mainly Indians who will not stand the full doses recommended for Europeans, and in such matters as the keeping properties of arsenicals in the Indian climate, but for a number of other drugs we are dependent almost entirely on the research work and clinical trials by workers in this and other tropical countries. It has been the tradition in our laboratories to work in the closest collaboration with scientists in this country and all over the world. We hope the Department 'Bayer' has been of some assistance to you, but I can assure you that your co-operation has been invaluable to us and on behalf of the research workers in our laboratories at Home and my colleagues here, I once more want to express our sincerest thanks for your active help in furthering the science of chemotherapy, the foundations of which were laid by that great man in whose honour we are gathered here to-day.

Lieutenant-Colonel Chatterji proposed that Colonel Chopra should be chairman of the meeting, and took the opportunity of congratulating him on the recent honours conferred on him—his admission as a member of the Royal College of Physicians of London, and his appointment as King's Honorary Physician.

Colonel Chopra took the chair and after thanking Lieutenant-Colonel Chatterji and all those present, he delivered an address on Paul Ehrlich and his work, as follows:—

The preparation and application of organic arsenicals in medicine, for which Paul Ehrlich was primarily responsible, were doubtless the result of a long and persistent search for substances which have specific action against disease. The advent of these compounds into the realm of medicine marked a new era in the history of rational development of therapeutics and the modern science of chemotherapy. At once, it opened up a new vista, pregnant with infinite possibilities, towards the one goal of medical science, viz, the amelioration of human suffering. Not only was this a definite step forward in the path of medical research, but it was a new departure, indeed a new acquisition to the armamentarium in our struggle against disease. The diseases which exacted a heavy toll of human lives, that ravaged towns and villages, and told adversely upon the culture and civilization of bygone ages, and which were in consequence looked upon as visitations from Heaven, due to sins of man, are no longer looked upon with awe and dismay, but with the spirit of triumph and victory on account of this work. These monumental contributions of Ehrlich rightly deserve a foremost place in the history of the fight of man against disease.

Paul Ehrlich was born in March 1854 in Silesia in Germany where the art of dyeing flourished as an old handicraft. He was, therefore, familiar from his boyhood with dyes and a story is told that when attending the microscopical courses as a young student in Strasburg, his teacher Professor Waldayer found, to his surprise, Ehrlich's place in the laboratory covered by a patchwork of stains of many colours, and asked him what he was doing. The answer was 'I am staining', whereon the teacher could only reply 'Well go on by all means'.

In his early life as a medical student Ehrlich was very much impressed with Heubel's work on lead poisoning. This work probably first gave him the basis for the idea that chemical agents have great influence upon living bodies in general and that 'the ways and means by which the drugs are distributed in the body must be of greatest importance' in therapeutics. This idea combined with the knowledge that in technical processes certain dyes were fixed by certain fibres gave a strong impulse to his research work in later years and led him into a series of studies upon the selective effect of various synthetic dyes on the blood and tissue cells. The results of such studies no doubt further led him to the conclusion that chemical substances might be produced which would unite with and destroy parasitic agents of disease without in any way injuring the cells of the host. It is this study of the selective affinity of chemical agents for parasites that led him to pronounce his famous theory '*Corpora non agunt nisi fixata*' which means 'bodies do not act unless fixed'—a theory that still lies at the basis of modern chemotherapy.

The development of the science of immunology with its discovery of natural and acquired antibodies, specially the discovery of the protective and curative action of the diphtheria antitoxin, strengthened Ehrlich's hope of finding out chemical agents capable of destroying parasites causing disease. Regarding the antibodies his idea was that 'they had no affinity at

all for substances of the body, but they rush exclusively at the parasites. Therefore in this case organotropy is reduced to zero, parasitotropy is absolute and the antibodies represent magic bullets which seek their unerring aim'.

Researches with dyes.—In 1887 acetanilide (antifebrin) and certain other substances were synthesized from coal tar and the use of these substances in medicine as antipyretics and analgesics still further stimulated him. Ehrlich began his work with the application of synthetic dyes to those bacterial infections that could be produced in laboratory animals like mice, guinea-pigs, rabbits, etc.; the line of study being the investigation into the manner in which immunity to such diseases could be increased in mice. Unfortunately his work with bacteria met with little success. He had, however, an infinite reservoir of patience and after a lengthy period of failures, which lasted till 1901, he at last came across Laveran's work on the production of trypanosomiasis experimentally in mice and rats. From that time onward Ehrlich and his co-worker Shiga directed their attention towards the trypanosome infection in laboratory animals. These parasites were then known to be responsible for causing sleeping sickness in the natives of Africa and to produce a disease in horses known as *mal de Caderas*. The incidence of death due to infection with these parasites in mice was one hundred per cent. Ehrlich and Shiga tried a large number of synthetic dyes on such infected animals, but the results were uniformly unsuccessful till at last they hit upon a dye known as *benzo-purpurin*. This dye was however without any effect, but by the introduction of a 'sulpho-group' into this they were able to synthesize a new compound that gave hopeful results in a few cases. This 'changed' dye was termed trypan red, but it was later found that the failures with it were perhaps more numerous than the successes, and that the efficacy of the drug was therefore doubtful.

But the perseverance and zeal of Ehrlich were unbounded. Success and failure were looked upon by him equally with enthusiasm so long as they were instrumental in gaining experience. In the words of Tennyson, to him 'all experience is an arch wherethro' gleamed that untravell'd world' and failures in particular instead of throwing him into despair goaded him all the more 'to follow knowledge like a sinking star beyond the utmost bound of human thought'.

Preparation of organic arsenicals.—Ehrlich's next line of attack consisted in the study of various pentavalent organic arsenicals on trypanosomes *in vitro* and he found that these compounds were all inert. In 1905, however, Thomas published the results of experiments showing that atoxyl had a curative action on laboratory animals infected with trypanosomes. Koch about the same time obtained encouraging results in the mass treatment of sleeping sickness with atoxyl among the natives of Africa. He found that, although atoxyl was not a certain cure for this disease, it often produced considerable improvement. The number of failures could not, however, be overlooked. Besides this the untoward effects produced by this drug, particularly the loss of sight among those who received treatment with it, were of serious significance. Contrary to the findings of its discoverer, Beauchamp, atoxyl was found to be 'para-amino-phenyl arsenic acid' containing pentavalent arsenic within it, and the activity of this compound, although it contained pentavalent arsenic, was regarded by Ehrlich as being due to the reduction of arsenic to the trivalent state within the body. With this theory as his basis, he started work on the study of trivalent organic arsenical compounds. Ehrlich's first attempt was to 'change' pentavalent arsenic in atoxyl to the trivalent form. This led to the preparation of many compounds and the search for suitable compounds went on incessantly in Ehrlich's laboratory. He himself and his assistants prepared one compound after another with atoxyl as the starting point and tested each compound on animals infected with trypanosomes. In this way this laborious process of preparation and testing continued and over 600 different

compounds were duly examined. Most of these were found to be ineffective, only one or two among them giving promising results. It was observed that although some of these compounds could cure trypanosomiasis, they unfortunately produced in some animals fatal hæmolytic, jaundice and other toxic effects. In the case of one drug it was found that it killed the parasites, but it damaged the nervous system of the animals to such an extent that the animals used to dance 'not for a minute or an hour due to their liberation from the clutches of the dreadful disease but for the rest of their lives'. After studies extending over many years with derivatives of atoxyl a compound, para-arseno-phenyl-glycine, was produced in which two arsenic atoms were linked by a double bond and each coupled to the benzene nucleus by a single linkage. This compound was in fact the precursor of the arseno-benzene compounds which were later found by him to be very effective. At last after a prolonged search he was in 1910 rewarded by the production of the 606th compound which was 'dihydroxy-diamino-arsenobenzol-dihydrochloride'. This compound had a most potent effect on the trypanosome in infected animals without at the same time injuring the host and the news of the great discovery soon spread throughout the scientific world.

Action of arsenicals on spirochaetes.—In the meantime the organism responsible for producing syphilis had been discovered by Schaudinn in 1906, who named it '*spirochaeta pallida*' and brought out the fact that it was closely related to trypanosomes. Indeed he went so far as to say that 'spirochaetes may sometimes turn into trypanosomes'. When Ehrlich came across this work the importance of the destructive action of his arsenical preparations on trypanosomes and their chemotherapeutic possibilities became apparent to him and he was led to announce '*Quod non sanat ferrum sanat arsenicus; quod non sanat arsenicus sanat ignis*' which means 'what iron does not cure arsenic cures; what arsenic does not cure fire cures'. Ehrlich's work received a fresh impulse when Paul Uhlenhuth in 1907 demonstrated the striking effect of atoxyl in fowl spirochaetosis, an action which was confirmed in collaboration with E. Hoffmann in experimental syphilis in monkeys. This strong conviction of his on the efficacy of arsenical preparations has, to a very great extent, come true as recent researches clearly point out. It was therefore very natural for him to try his compound no. 606 in this disease also. He justified this attempt of his by saying 'If the pale spirochaete is a cousin of the trypanosome of the *mal de Caderas* then 606 ought to hit that spirochaete.... What kills trypanosomes should kill their cousins'. In this way Ehrlich and his co-worker Hata first tried this drug on a rabbit infected with spirochaetes and that rabbit was the first living being completely cured of the disease. This, however, is the short history of a long research requiring years of patience, and perseverance amidst failures and anxieties and culminating in the discovery of 'Ehrlich 606'.

It will be seen, therefore, that the drug 'Ehrlich 606' was primarily discovered to fight trypanosomes and it was later found to be useful in the treatment of syphilis. The action of this compound against two of the most dreadful diseases impressed the scientific world and the drug was examined by both chemists and pharmacologists alike who confirmed Ehrlich's claims. This compound is said to have a dibenzol or arsenobenzene nucleus coupled together by two trivalent atoms of arsenic. The nucleus itself is of no therapeutic value and is of interest only because it is the parent substance of salvarsan. By a multiplicity of changes, syntheses and experiments attempts were made to determine which atoms or groups of atoms and what grouping in the molecule increased its affinity for the parasites and reduced its toxicity to the cells of the host. It was found that substitutions in the NH₂ group may cause profound differences in the effect of the compounds, sometimes an increase and sometimes a decrease in the therapeutic effect.

Preparation of neosalvarsan.—On the 20th of September 1910 when Ehrlich's discovery was officially made known to the world, his friend Neisser remarked that naturally the first discovery cannot be expected to be perfect in every respect, but that it was hoped that the preparation 606 would be followed by a still better preparation 607 or 608. Neisser, however, was too optimistic when he expected that the next two preparations were going to solve the question. Years of further patient and laborious work were required until the preparation 914 or neosalvarsan (which is a condensation product of salvarsan and sodium formaldehyde sulfo-oxylate) was discovered. This compound is sodium 3:3 diamino-4:4 dihydroxy-arsenobenzene-methylene-sulphinate and it is derived by the introduction of the methylene sulphinic group into one of the two amino-groups. This new compound satisfied many of the requirements demanded from such drugs, viz, decreased toxicity, and has a neutral reaction. The fact that it is nearly 2.5 times less toxic than salvarsan and the ease in manipulation has increased its popularity although its keeping powers are not so great; its solution oxidizes readily on shaking and its toxicity, and therapeutic efficiency are also apt to vary in different samples (Dale and White). In fact, its precise structural composition is still uncertain; Ehrlich merely described it by stating that it was obtained from arsephenamine by the action of formaldehyde sulfo-oxylate. Nevertheless it was a distinct improvement on the former compound and is at present being used extensively by medical men throughout the world. Attempts have been made and are still being made to find out a stable variety of this compound that will prove to be even more satisfactory from a therapeutic point of view and less toxic. Of all these the silver sodium compound of salvarsan or neosalvarsan has a high chemotherapeutic index but therapeutically it is no more effective. All other compounds of this nature that have been obtained up to now have however no special advantage over neosalvarsan.

Arsenical preparations in therapeutics.—The far-reaching effects of Ehrlich's work cannot be overestimated. Although admittedly the *therapia magna sterilisans* that was expected to follow on the heels of 606 has not matured, the development of the science of chemotherapy, of which salvarsan was the first striking success, has placed within the reach of the physician many potent remedies against disease. To the physician in the tropics, Ehrlich's researches have directly or indirectly given many specifics for diseases, such as kala-azar, trypanosomiasis, syphilis, yaws, etc., which were considered incurable. Other diseases such as rat-bite fever and relapsing fever which produced much incapacity can now be cured with a few injections of arsenobenzene compounds.

Ehrlich's work on the organic arsenicals has been carried further by other workers. Not only were further possibilities of the trivalent compounds explored, but a comprehensive study of the pentavalent compounds was pursued with gratifying results. In this way another compound, tryparsamide (sodium-n-phenyl-glycinamide-p-arsenate), was discovered at the Rockefeller Institute, New York, which is useful in the later stages of trypanosomiasis and syphilis when the parasites have penetrated into the central nervous system. Fournneau and his colleagues at the Pasteur Institute, Paris, produced a series of compounds of which Fournneau 270 (sodium-4 acetyl amino-2-hydroxyl-phenyl-arsenate) and Stovarsol (sodium-3-acetyl-amino-4-oxyphenyl-arsenate) are well known. These compounds are of particular interest since not only did they throw light on the relationship between chemical constitution and parasitic action, but led to the production of certain compounds which are effective when administered by the oral route. Although these particular compounds had a limited degree of success in curing syphilis and trypanosomiasis, they opened up for the physician fresh possibilities in oral therapy. The result has been rediscovery of the compound carbarsone (4-carbamino phenyl arsonic acid) which

was originally prepared by Ehrlich and which was discarded by him because it did not have any marked trypanocidal properties. This compound in doses of 0.025 gm. twice daily for 10 to 15 days cures a large percentage of cases of chronic amœbiasis which were not touched by emetine and its derivatives. The introduction of carbarsone into tropical therapeutics marks a definite advance in the treatment of this widespread disease.

Ehrlich's basic work on dyes, although it gave him disappointing results, has been responsible for the production of such powerful drugs as Bayer 205 which has proved effective in the treatment and prophylaxis of trypanosomiasis and Yatreñ 500 which is an effective remedy against amœbic and bacillary dysentery. The preparation of powerful antimalarial remedies such as plasmochin and atebrian by Professor Schulemann of Bayer-Meister Lucius and his co-workers, which has changed our whole outlook of this world-wide disease, followed indirectly upon Ehrlich's work.

The series of organic compounds of antimony we also owe to his researches, because it was working on the lines of Ehrlich's work with the preparation of organic arsenicals that Professor Schmidt, at that time working with Von Haydon's firm, produced the antimonial compounds which led eventually to the preparation of urea-stibamine and neostibosan which are effective against leishmaniasis, and antimosan and foudain which are effective against the dreaded schistosomiasis.

Organic arsenicals themselves have been tried in the treatment of widely different diseases and, although they have not produced uniformly successful results, further studies may lead to the production of compounds having a specific action against disease. For instance experiments on bacterial infections show that arsephenamine compounds when injected into animals confer upon the blood bactericidal properties that are retained therein for a considerable time. The serum of patients after injection of arsenicals exerts a bactericidal effect upon staphylococci and hæmolytic streptococci. Further work in this connection may lead to interesting and important developments. In helminthic diseases although the arsenicals do not produce uniformly successful results, a few intravenous injections may often give relief against trichinosis and filarial infections.

Such is a brief account of Ehrlich's researches and their achievements in the domain of medical science. It will not be too much to say that so far as protozoal diseases are concerned the effects have been remarkable and further progress is expected. Hosts of workers are following in Ehrlich's footsteps and chemotherapeutic research is making rapid strides. The discovery of salvarsan is not only a pioneer work but a distinct landmark in rational development of therapeutics. The preparation of this single compound has given chemotherapy a solid foundation on which it now stands. It has supplied the practitioner with missiles with which he can wage war against parasites which produce disease and suffering in man and animals. It has raised chemistry at once from being a science necessary for human comfort to one that can save mankind from its microscopic enemies.

Lieutenant-Colonel Chatterji then addressed the meeting:—In my student days I used to hear of Paul Ehrlich, of him as a man and his wonderful contributions to the science of medicine. Reading about a person is one thing but seeing him is something very different and I have always been addicted to indulge in the curiosity of seeing the person I had read about, and I wondered then whether I would ever be able to meet this great man. For once, luck was in my favour, and I found it possible to go abroad to see things and to learn what I could from seeing. In 1908, I found myself in the august presence of Paul Ehrlich. It was at a meeting of medical men and Ehrlich turned up there most unexpectedly; let me be frank and admit that his advent was an inspiration to me. A little man, rather thin with a genial face and even more genial

smile; there was an air of sadness in his features which may be explained by the virulent criticisms levelled against him by other scientists. His eyes were remarkable; they were bright with an intensity of life which seemed to glow from them. I think he told me that he never despaired and that no one should ever despair. Like an expectant mother he was looking forward to a successful issue of his investigations. With Brahmanical instinct I wished for blessings for his success. That success came, success always comes to the deserving, like Paul Ehrlich. A weary traveller, he travelled the paths of research, working and achieving and giving the results of his achievements away for the advancement of science; such gifts are like milestones of silent mementoes of his scientific work which led to amelioration of human suffering.

This day, 25 years ago, Paul Ehrlich addressed a meeting of scientists and members of the medical profession at Frankfurt and made the momentous announcement that '606' had achieved what he had hoped it would achieve. He christened it 'salvarsan' and rightly so. It is truly salvation (sanskrit equivalent, *paritran*) because it not only meant salvation of the individual sufferer, but it has brought salvation to nations all over the world from the ravages of a disease which cripples, maims, incapacitates and invalidates through the destructive propensities of its causal parasite, pretty to look at, delicate in its movements but endowed with powers of invasion of every structure of the human host. More than that, it can lie fast and latent in the most intricate parts of the human body and has the unique capacity of transmitting itself from one human generation to another. This familial transmission seems to be its birthright and environmental protection its latent safeguard. From time immemorial weapons have been devised for the destruction of *Treponema pallidum* but it was left to Ehrlich to find in '606' the most formidable among them, thanks to his genius, undaunted courage and perseverance.

Paul Ehrlich was instinctively an investigator, originator of ideas and a philosopher; a man of great imagination, imagination which was creative and productive. There is no finality in research and Ehrlich knew that. I believe he was contemplating a voyage East and West, to the tropical regions to make a further study of the disease for the cure of which he had discovered '606', but the cruel war interposed and his work was interrupted. He might have got some information from his understudy, Hata, and from the Hamburg Institute of Tropical Hygiene. How I wish he had come to India, because the more I see, the more I appreciate the vagaries in the manifestations of the disease tainted with tropical infections and during my last sojourn to the West I wandered about in search of facts in relation to this disease influenced by tropical conditions. I collected some and presented them to research departments here for investigation and study. But this, the most killing of diseases rendered even more killing by tropical infections, did not seem to be included in the departmental nomenclature of diseases. There seems to be an apathy towards this and sooner it is shaken off the better it is, for this and other tropical and subtropical countries. It would be difficult to find a Paul Ehrlich again, but lesser Ehrlichs may be found who could pick up the thread where he left it and work for the solution of this great problem.

This is neither the place nor the time for entering into the posology and therapeutics of '606', but I shall just tell you a few things that trouble me. The manifestations of this disease are most varied. It is a great mimic and to be misled is not difficult. Then the toxicity of the drug in some cases and its inaccessibility to the parasite in arsenic-resistant cases are further puzzles. Familial and third generation transmissions, their vague, indefinite and uncertain manifestations are difficult problems. Ehrlich has brought salvarsan as a rare gift to the medical profession; it is a good and powerful weapon, but let us not forget that in fighting a formidable and subtle enemy like the treponema,

while '606' may make the frontal attack, we have other weapons like mercury, bismuth and iodine for rear and flank attacks and the much condemned air bombing. We may use these simultaneously or alternatively as surprise attacks. The eradication of the infection is indeed a difficult problem. Ehrlich is not here to make further gifts to solve these problems, but whoever does will bring *paritran* to our land.

Gentlemen, in treating a patient to cure him of this disease, begin in the beginning and go on till you think you have come to the end of treatment but do not stop lest you may have to begin over again.

Dr. Brocke then spoke again:—

The addresses of two so distinguished workers have given us very vivid impressions on the great scientist's career and I feel that this is the occasion to present to the speakers two replicas of the memorial tablet erected in Paul Ehrlich's study in the Georg Speyer-Haus and State Institute for Experimental Therapy in Frankfurt. I feel greatly honoured that I am allowed to do so and that I am to convey the sincerest greetings of the research workers of Bayer at Home whose names—like Dr. Schulemann, Dr. Hoerlein and Dr. H. Schmidt—are not entirely unknown to you.

The memorial tablet in Paul Ehrlich's study bears the Latin inscription *CHEMOTHERAPEUTICS POSTULATUM PRIMUM UT PROFICIATUR. PRIMO PROXIMUM UT NIL NOCEATUR* (For a chemotherapeutic it is the first postulate that it should cure but the very next one that it should not do any harm), a principle which has always been and we hope will be the guide of research work all over the world as a living heritage of Ehrlich's work.

He presented the two medallions.

A very excellent cinematograph 'talking' film describing and illustrating the history, the symptomatology, and the treatment and cure of syphilis was shown.

Colonel Chopra then closed the meeting by thanking Dr. Brocke and the scientific department of Bayers for organizing the meeting and for the replica medallions that he had presented to Lieutenant-Colonel Chatterji and himself.

EXTRACTS FROM THE MINUTES OF THE BENGAL COUNCIL OF MEDICAL REGISTRATION HELD ON THE 18TH FEBRUARY, 1935*

1. THE remarks offered by the authorities of the undermentioned medical schools on the Inspection Committee's observations recorded on inspection were referred to the Committee for consideration:—

- (i) Ronaldshay Medical School, Burdwan.
- (ii) National Medical Institute, Calcutta.
- (iii) Bankura Sammilani Medical School, Bankura.

2. It was reported that nomination papers were issued to the members of the Council for the election of a representative of the Council on the Bengal Nursing Council and as a single candidate Dr. Bidhan Chandra Ray, M.D., M.R.C.P., F.R.C.S., was nominated for this election he was reported as elected. The action taken by the office was approved.

3. Government resolution announcing the appointment on the Bengal Sanitary Board of Dr. Taraknath Majumdar, L.M.S., D.T.M., D.P.H., F.C.S., and Dr. Abdul Majed, M.B., D.T.M., D.P.H., representatives of the Bengal Council of Medical Registration and the State Medical Faculty of Bengal, was recorded.

4. Report on the inspection of the Campbell Medical School was adopted.

5. Report on the inspection of the Jackson Medical School, Jalpaiguri, was considered and adopted and it was decided that the authorities of the school should be asked to stop admissions and that the question of its disaffiliation be considered by the Council at their

* Forwarded for publication under letter dated 15th November, 1935.

next meeting and that Government be informed of the decision taken.

6. Government letter authorizing the entry of the title 'Fellow of the State Medical Faculty' in the Register of Registered Practitioners as an additional qualification was recorded.

7. The consideration of the report on the revision of the appendix to the Annual Medical List was postponed.

8. Government notification announcing the acceptance of the recommendation of the Council that the M.B., B.S. degree granted by the Andhra University be recognized as registrable under section 18 of the Bengal Medical Act, 1914, was recorded.

9. It was decided that the qualification D.B. (London) be entered as an additional qualification against the name of Dr. Ganapati Panja, M.B., in the Register of Registered Practitioners.

10. The consideration of the application of Dr. M. R. Treu, M.D. (Cologne University), for registration of his name under the Bengal Medical Act, 1914, was postponed for the next meeting.

11. Government notification announcing the election of Dr. Bidhan Chandra Ray, M.D., M.R.C.P., F.R.C.S., under clause (c) of section 4 of the Bengal Medical Act, 1914, was recorded.

12. On an application from the Registrar, Andhra University, it was decided that a report be made to the local Government under section 18 of the Bengal Medical Act, 1914, recommending that the L.M.S. diploma granted by the University be recognized as registrable in Bengal.

13. On an application from the Registrar, University of Rangoon, it was decided that a report be made to the local Government under section 18 of the Bengal Medical Act, 1914, recommending that the L.M.S. diploma granted by the University be recognized as registrable in Bengal.

14. An application from the Principal, Ludhiana Medical School, praying for recognition of the school as an institution eligible to train and send up candidates for the Licentiate Examinations of the State Medical Faculty of Bengal up to the Intermediate standard was refused as there was already a Medical Faculty in the Punjab.

15. It was decided that the Dacca Medical School and the Lytton Medical School, Mymensingh, should be critically inspected during the next 6 months.

16. The consideration of the returns submitted by the recognized medical schools was postponed for the next meeting.

17. With regard to the publication of the Annual Medical List it was decided that it should henceforth be corrected up to the date it goes to press.

18. With regard to an application from the authorities of the *Medical Bulletin*, Bombay, it was decided that copies of such proceedings and resolutions as are intended for the medical press may be supplied for publication in the *Bulletin*.

19. The undermentioned gentlemen were re-appointed members of the Penal and Ethical Cases Committee for the year 1935:—

Lieutenant-Colonel T. C. Boyd, D.P.H., F.R.C.S., I.M.S.

Dr. J. N. Moitra, M.B.

Sir K. N. Das, Kt., C.I.E., M.D., F.C.O.G.

Dr. P. Chatterjee, M.B., F.R.C.S.

Dr. A. D. Mukherjee, L.M.F.

20. Considered two reports of the Penal and Ethical Cases Committee.

21. Dr. J. C. Chatterjee, L.M.S., was re-appointed a member of the Managing Committee of the Provident Fund of the Office.

22. Dr. K. S. Ray, M.A., B.Sc., M.B., Ch.B., was appointed a member of the Inspection Committee *vice* Dr. Mrigendralal Mitra, M.D., F.R.C.S., deceased.

23. With regard to an application from Mrs. Kusumkumari Majumdar, L.M.P., L.M., praying that her M.D. (Berne) qualification be entered against her name in the Register of Registered Practitioners as an additional qualification it was decided that particulars

regarding this degree should be obtained from the University.

24. Entry under section 21 of the Bengal Medical Act, 1914, of the qualification D.T.M. & H. (England) against the name of Dr. Francis John Copeland, M.B., Ch.B., was approved.

25. The raising of the fee for registration of an additional qualification from Rs. 5 to Rs. 25 and the price of the Annual Medical List from Rs. 3 to Rs. 5 per copy was agreed upon.

26. The following motion of Dr. Amulyadhan Mukherjee, L.M.F., was referred to the Inspection Committee:—

'This Council is definitely of opinion that in institutions recognized by this Council each subject excepting Medical Jurisprudence and Hygiene must be taught by separate teachers as is done in the Medical Institutions of Calcutta and Dacca'.

TROPICAL DISEASES BULLETIN

Tropical Diseases Bulletin. Vol. 32. Supplement. Nov., 1935. 280 pp. 'Medical and Sanitary Reports from British Colonies, Protectorates and Dependencies for the Year 1933' summarized by H. Harold Scott, M.D., F.R.C.P., D.P.H., etc., Director of the Bureau of Hygiene and Tropical Diseases. [Price 7/6.]

This fifth annual issue of the 'Medical and Sanitary Reports from British Colonies, Protectorates and Dependencies for 1933' contains an account of the activities of 55 medical services within the British Colonial Empire. The reports record the progress made in health work during the year in the face of the difficulties of controlling disease among backward populations under unfavourable economic conditions. The main lesson that comes out of a study of the summaries is that in the tropics, as at Home, real improvement in health among the population is bound up with improvement in agriculture, housing, and education and the raising of the general standard of living, and to bring this about wise and informed administration at the head and harmonious co-operation between the different government departments are essential. The medical departments are shown by their reports to be making their contribution towards the general economic advancement of the native communities in the British colonies by providing medical facilities for curing disease, by prosecuting research into the causes of disease and methods of diagnosis and prevention, by developing health services such as maternity and child-welfare work, school hygiene, and general sanitation, and by arranging for the training of natives as dispensary assistants, sanitary inspectors, nurses, and midwives and in some colonies as doctors, to take their proper share in caring for the health of their own people.

The usual table of vital statistics for British Colonies, Protectorates and Dependencies during 1933 which is appended brings out the lack of reliable data from many parts of the Colonial Empire and the need for a much improved system for the collection of vital statistics in certain British colonies.

INDIAN MEDICAL COUNCIL

In pursuance of the proviso to sub-section (2) of the Indian Medical Council Act, 1933 (XXVII of 1933), the Governor-General in Council is pleased to nominate Major-General Sir Frank Powell Connor, Kt., D.S.O., F.R.C.S., D.T.M. & H. (Eng.), L.R.C.P. (Lond.), K.H.S., I.M.S., Officiating Director-General, Indian Medical Service, as the President of the Medical Council of India, with effect from the afternoon of the 29th October, 1935, *vice* Major-General C. A. Sprawson resigned.

Colonel H. C. Buckley, M.D., F.R.C.S. (Edin.), I.M.S., Inspector-General of Civil Hospitals, United Provinces, has been nominated by the Government of the United Provinces under clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India *vice* Lieutenant-Colonel H. Stott, I.M.S., resigned.

On Some Aspects of Contraception for Indian Women

By MARIE C. STOPES, D.Sc., Ph.D., F.L.S., etc.

(From *Marriage Hygiene*, November 1934, Vol. I, p. 143)

THERE are many good reasons why Indian women should want to know about methods by which they can safely control conception. The reasons are the same as for the women in England and elsewhere. It is not a class matter but a physiological need. However rich a woman may be, her own strength cannot stand rapidly repeated pregnancies without some result of loss in vitality, and hence suffering for the child. Anyone requiring to be argued with about the need for contraception should read my simple, persuasive little book *Wise Parenthood*, or the more detailed book *Contraception, Its Theory, History and Practice*. The methods described in these books are universally applicable, but India has some special problems and in this article I propose to mention one or two points specially for Indian women. The great heat, the distance from supplies, and the extreme poverty of large numbers of the Indian population have to be considered.

Wealthy women are a comparatively small number. It is the poor women of India, the vast majority, for whom special methods must be devised. These cannot be fitted; they cannot afford the price of a rubber cap; probably they could not be relied upon to place it accurately each time. Even the simple sponge and oil method described in my book *Birth Control To-day* is too expensive and the sponge is unobtainable. I have, therefore, thought out a special substitute adapted for the poorest Indian women. This method has the advantage that it costs nothing at all. She does not need to go to any special shop or person to buy anything for she can make what she requires herself in her own home from the things she has in the home. Though the method is so simple it is really a very good and reliable one if used carefully.

The woman should take a small handful of cotton waste. This is not to be confused with what the Europeans call 'cotton-wool'. Cotton-wool is white, prepared, comparatively expensive and loses all its springiness when it is wetted. Cotton waste from her own spinning is springy and soaks up the oil without becoming sodden and flat. It is there without expense. The woman should take enough of the cotton waste and make it into a little pad the size of the palm of her own hand and about the thickness of the end of her own thumb. The waste can be held together by lightly winding threads criss-cross like a spider's web so the tufts do not fall apart; or if clever she can crochet a little net for herself into which the pad can be fitted. Then into a cup or small bowl she should pour a little of her ordinary cooking oil. This oil must be a bland one, not mustard oil, but any bland cooking oil she is using. The pad soaks it up and then she should lightly squeeze the pad to drain off the extra oil so it does not drip. This is then inserted high up in the vagina just before she goes to bed. It should be pinched somewhat together until it is up and then should spread out and tuck round the neck of the womb at the end of the vagina. The pad and the oil together form a barrier past which the fertilizing spermatozoa will not be able to enter. It is best to insert this before going to bed so as not to disturb the romantic feeling and peace which sex union should engender. It should remain there in place until the next morning when it can be taken out while dressing and burnt. If the waste has been enclosed merely in loose threads then the whole thing can be burnt, but

if the pad of cotton waste has been enclosed in a specially made net, then the net may be preserved and washed, but if so it ought to be boiled to be really clean. It is probably better to hold the pad together with lightly bound threads and burn the whole thing.

The woman must realize she must not remove this pad immediately after the act of union has taken place, for the grease must be allowed thoroughly to deal with the spermatozoa. If removed too soon it would give them an opportunity of swimming in, but if left until the next morning it is almost certain all the spermatozoa would be rendered useless by that time.

There will probably be a good deal of opposition to the spread of knowledge of a method so simple and inexpensive, for unfortunately contraception affords a source of profiteering wealth to many commercial interests. But I trust that this message to poor Indian women may reach them and save them from needless fear of undesired pregnancy and from a needless dependence on commercial interest.

For the well-to-do Indian woman, educated, and with sufficient money to spend on hygienic requirements, some scientific and precise method may be better suited. There are various types of rubber barriers or caps, for example the 'Racial' occlusive or the 'Clinocap', Dutch diaphragm, or other makes which should be selected according to her internal conformation. Anyone of these, if she can get instruction in its proper fitting, is quite suitable. The difficulty of getting the proper instruction, however, bars the cap from use by many women who would otherwise like to, and can quite well afford to pay the couple of shillings that it costs. But it is inadvisable to use it without proper instruction. Some women who have had instruction in the use of the cap and wish to carry on with the cap that suits them, and use greasy suppositories with it, and who wish to continue to get supplies from England, find that the greasy suppositories melt in transit. There are many commercial firms who, knowing this, sell greasy suppositories 'specially made for the tropics'. These may arrive in good condition and the woman may not know enough to realize that the very fact that the grease was hard enough not to melt in transit shows it is unsuitable for the purpose, for the internal temperature of a woman does not depend on external temperature, and a woman in the tropics needs just as low melting-point grease as she does in a cold climate. To overcome this great problem I have been looking into the matter of internal temperatures and melting-points of odourless grease and we have now at our clinic specially coated low melting-point grease, the coating of which also melts internally after having been dipped in cold water. These, called the 'Clinocap' solubles, are specially adapted for use in the tropics and a wealthy woman who wants to go on using the technique she has been taught in Europe can easily do so if she uses these 'Clinocap' tropical solubles which she can get from my clinic direct.

It is greatly to be desired that a service of properly trained Indian medical men and women and qualified midwives should receive technical instruction not only in the art of choosing the right contraceptive and fitting it for each patient, but also in the art of teaching patients how to apply the method themselves. For contraception differs from other medical matters in depending much more on the patient than do most medical measures. The woman using any contraceptive must use it accurately every time and must be taught the importance of care.

Technical instruction in contraceptive technique with demonstrations and practice on living models were initiated by me at the Society for Constructive Birth Control Headquarters in London, 106 and 108, Whitfield Street. If any wealthy Indian wants to serve his or her country I suggest that an endowment sufficient to send out a C.B.C. trained nurse and doctor to institute centres of instruction in India would be the greatest boon. Our society is ready with technique and staff; money only is needed to provide this service for which Indian motherhood is crying out.

The Care of European Children in the Tropics

By H. S. STANNUS, M.D., Ph.D., F.R.C.P., D.T.M. & H.
(From the *Practitioner*, Vol. CXXXV, August 1935,
p. 138)

It is not perhaps always realized by those who dwell in temperate zones how extreme may be the variations in climatic and other conditions present within the tropical belt. Climatic conditions depend in large part not only upon latitude but also upon altitude, the general conformation of the country, rainfall, prevalent winds, and humidity. On the one hand may be found areas in which European children can be reared in comparatively healthy conditions. On the other there are regions in which conditions to child life are extreme. In this article it is proposed to deal with the conditions commonly found in East and West Africa, in many parts of India and elsewhere; and a rough division will be made between the infant from birth to two years of age and the child from two to seven years of age.

Care of the infant, and in great part of the younger child as well, may be defined as the sum of all those methods which can be adopted to protect it from adverse factors in its environment. Since the infant is practically a non-motile organism, just as it lacks ability to search for its food, so it lacks the power to avoid approaching danger and the power of self-defence. In the same way it is unable to change its circumstances in response to heat and cold and is, in a sense, a poikilo-thermic animal, a point of vital importance in hot countries. Care of the child spells attention to detail: care of the child in the tropics spells attention to every detail by the mother, an onerous task.

The infant's clothing will be much the same as that during the summer months in a temperate country, the cot coverings being varied according to the season. The cot, which should be roomy and larger than those used in this country and of bedstead form, is best placed in the middle of the nursery. The room is preferably mosquito-proofed and well ventilated, and should be as barely furnished as possible, thus avoiding all shelter to mosquitoes. The mattresses should be firm and flat, and the bed-clothing as light as need be, so that the child is secured freedom of movement and fresh air. The same is necessary in the arrangement of the perambulator. Most infants and children in the tropics are, I think, overclothed. The cot or bed is fitted with a mosquito net of such a texture as to exclude not only mosquitoes but midges and sandflies, and so arranged that no part of the child's body or limbs can come in contact with it. Except the infant be under the eye of the mother or other trusted person, it should be similarly protected when in its perambulator. A constant circulation of air about the child should be sought and in some cases it may be necessary to employ artificial ventilation by punka or fan. On the other hand, means must be adopted to protect the child from chilling, when, as sometimes occurs, a fall of as much as 40°F. in temperature may take place between the evening and early morning. For younger children 'chilprufe' fabrics find a useful place. A child should never be allowed to soil its fingers on the floor, and never go unshod. Dummies should be disallowed.

The infant's toilet will not differ materially from that in any other part of the world; in hot weather the bath should be cooler and *vice versa*; cool sponging and later a cold shower are most useful for their general tonic effect and will not harm the healthy child. The greatest care should be taken to instil into the young infant a regular habit in evacuation of bowel and bladder so that soiling is avoided; further, scrupulous care is essential in changing soiled napkins, as the skin is very easily irritated in hot climates.

Although in this country the beneficial effects of the play of fresh air and of sunshine on the skin of the child are now well recognized, in most tropical countries

there appears to be a kind of superstitious fear in this regard, which is, in my opinion, much to the disadvantage of the child. Careful daily exposures to sunlight in the early morning, before the heat rays are too powerful, so that the body and limbs become well pigmented would, it is believed, do much to preserve the health of the child and acclimatize it to some of the factors of its tropical environment.

'Sunstroke' associated in the minds of most people with the actinic rays of the sun can no longer be looked upon as a clinical entity; all the effects direct and indirect of the sun's rays are due to overheating, and symptoms are just as likely to appear in those unexposed to direct sunshine. The danger point is a shade temperature of about 120°F. It is unlikely that children will be kept in such a climate, but lesser degrees of 'heat exhaustion' and 'heat hyperpyrexia' may be seen and demand immediate measures. The value of headgear is not to protect from 'sunstroke' but to obviate local heating effects and to give shade to the eyes.

Children living in the tropics not uncommonly suffer some degree of psychological disturbance. The single-child family, over-anxiety on the part of the mother, the presence of menial servants, over-stimulation and excitement, and insufficient sleep are all common factors in warping the child's outlook, but with care may be guarded against; a well-ordered life for the child is essential.

Feeding

All the reasons that have been urged in favour of breast-feeding in temperate climates hold good in the tropics where they are of paramount importance. It is therefore the more unfortunate that a large number of mothers in warm countries for many reasons are only too anxious to escape this duty; thus the medical practitioner, intent on doing his best for the child, will find his office a difficult one. In many cases the difficulty in maintaining breast-feeding is a real one, but if adequate care of the pregnant woman has been taken by ensuring a healthy mode of life, the exclusion of infection, the preservation of good bodily tone, the provision of a diet adequate in mineral salts and vitamins, the assimilation of a sufficient amount of fluid and the acquisition of a contented mind free from worry, their number should be reduced. The same care of the mother during lactation is necessary, each of the points above mentioned being of great importance in hot climates. Excessive cigarette smoking must be disallowed and only a minimum of alcohol permitted.

Details of breast-feeding will not be dealt with here, but the general principle of 3-hourly feeds, *i.e.*, at 6, 9, 12, 3, 6 and 10 o'clock for an infant of 10 lb., and 4-hourly feeds at 6, 10, 2, 6 and 10 for one over 10 lb. may be adhered to. In temperate countries the fluid intake required by the infant is approximately the same as the food (milk) intake, *i.e.*, about 2½ oz. per pound body-weight per day; on hot days the quantity of fluid required may be twice that amount. In the tropics the quantity of fluid necessary may be three or four times as great. This extra fluid, required above the milk intake, is best supplied in the form of half-strength normal saline. A common sign of insufficiency of fluid intake is staining of the napkins by the concentrated urine. Older children occasionally drink too much water (plain) and get diarrhoea in consequence.

Wet nursing appears to have gone out of fashion in tropical countries, just as it has here at Home. If adopted the greatest care in the selection of a native nurse must be exercised, as mentioned later when speaking of native servants.

Artificial feeding may be necessary to supplement or replace breast-feeding. In those areas where fresh cow's milk is available it is probably to be preferred. Details of the modification of cow's milk for infant feeding do not come within the compass of this article but it should be remembered that the constituents of cow's milk may vary considerably according to their

feed in tropical countries. The same applies to the milk of other animals which may be used—goat, buffalo, camel, ass.

All milk must be sterilized: while it is often possible to do something towards ensuring cleanliness in regard to the supply from animal to infant, the dangers of contamination are so manifold in hot countries that sterilization by heat and preservation from further contamination at a low temperature are essential. The dangers attendant upon a milk supply from a single cow are well known. The possibility of 'melitensis' and 'abortus' infections must not be lost sight of. Sterilization of milk, with some diminution of vitamin content, being essential, the addition of vitamins to the infant's dietary becomes necessary, and every baby should certainly after three months be given a drachm of cod-liver oil or its equivalent and two or three drachms of orange or tomato juice per day.

When fresh milk is not available, and this applies commonly during a voyage or long journey, recourse must be made to some proprietary milk preparation. Such preparations fall into several categories: (1) Sweetened full-cream condensed milk. (2) Unsweetened full-cream condensed milk. (3) Sweetened skimmed condensed milk. (4) Dried milks. No. 1 combined with a little cow's milk and cod-liver oil is sometimes useful. No. 2 with the addition of sugar and vitamins is an easily digested preparation. No. 3 is unfit for infant feeding. Under no. 4 a large number of preparations are on the market; their advantages are obvious. They are as a rule easily digested but vary somewhat in composition; each is useful in particular cases. Vitamins should be given when dried milks are used. Cow and Gate, Glaxo and Lactogen preparations are popular and brands specially prepared for tropical consumption are available.

Animal milk in tropical countries may be deficient in mineral constituents and the well-known bone and vegetable broth may be introduced into the diet of the infant with advantage at an earlier age than in temperate countries. The iron content may also be low and the anæmia of infants, one which responds to iron, should be borne in mind.

The feeding of older children needs no comment beyond again insisting on the need for the greatest care in the preparation and preservation of foodstuffs from contamination by dust, flies, and ants, upon the most scrupulous cleanliness of vessels and upon the effective sterilization of drinking water.

The amount of fluid required by a child at rest to replenish that lost via the skin is large and not always realized; with exercise this amount is far greater still. Fluid replenishment is best taken in the form of half-strength saline. An adequate supply of vitamins to the older child must also be ensured and may usually be obtained with a little ingenuity. Raw vegetables and fruits, which may be completely taboo in some countries, may be allowed where the conditions of production are certainly known and satisfactory. The danger of helminth and other infections should be remembered.

The prevention of bowel infections is, as elsewhere, a question of cleanliness of the food supply and non-contamination by insects, dust and the hands of native servants. The strictest supervision of the house, the larder, the kitchen and the compound should be observed. Flies and ants will come where food is available, where filth is allowed to collect, where garbage and refuse are exposed, where excreta remain undisposed. It is therefore a matter of compound sanitation. Rather in the same way evidence has been adduced more recently to show that the infection in malaria is commonly acquired from mosquitoes inhabiting the house and precincts, the same being true of other mosquito-borne diseases: if the house is kept free of mosquitoes, the risk of infection is greatly diminished. If the house possesses a second story the child should inhabit the upper rooms.

Infection

The reservoir of infection lies in great part in the native, in malaria mainly in the native children: it should therefore be an axiom that natives should not be allowed to reside in European quarters of a township, as far as possible, and native children should be rigidly excluded.

The local incidence of particular diseases will demand special precautions which cannot be detailed here, it is only necessary to call to mind the leishmaniasis, the relapsing fevers, the tropical typhus fevers, the filariases, and trachoma. Protection from insect vectors is the obvious line of defence.

It would be a good thing if all native servants could be medically examined. Watch could be kept for the common tinea infections of body skin, crutch, scalp and feet; for scabies, often found affecting the inter-natal cleft in natives; for chigger infection of the feet, and lastly for venereal diseases and yaws. In some areas the native population is nearly 100 per cent infected with syphilis, in others yaws claims a full 100 per cent, while in others again gonorrhœal infections are universal. The extremely common worm infections among the indigenous inhabitants of many countries also must not be lost sight of, and the method whereby infection is contracted remembered, if these infestations are to be avoided.

The watchword as regards the infant should be under all circumstances Prevention: with older children this may be more difficult. In regard to malaria quinine prophylaxis may be adopted, chocolate-coated preparations of quinine or euquinine (quinine ethylcarbonate) in condensed milk are useful; atebirin is also well borne by children. It is perhaps unnecessary to refer to the symptomatology of the many diseases in children, but the liability to the rapid development of fatal convulsions in infantile malaria must always be kept in mind. In the same way it must not be forgotten that the predominating symptom of bacillary dysentery in children is a toxæmia associated with convulsions and coma. This affection, however, in children often responds well to serum therapy. The differential diagnosis of diarrhoea in children under the headings dietetic, symptomatic and infective will always demand great circumspection. It is useful to remember that, certainly in most tropical countries, amœbic dysentery is very rare in children and that the danger of dehydration in diarrhoeal diseases among children in hot climates cannot be overestimated.

The care of European children in the tropics is no light task; it makes heavy demands on the mother and it will sometimes tax the knowledge and skill of the medical practitioners.

The Cod-Liver Oil Treatment of Wounds

By J. P. STEEL, M.D.

(Abstracted from the *Lancet*, 10th August, 1935, p. 290)

BURNS are seldom received at a hospital without first-aid treatment having been given outside, usually in the form of an oily dressing applied to the burnt area; for this reason the tannic acid method is not often applicable without extensive skin toilet, requiring in many cases a general anæsthetic. Picric acid is also extensively used for its analgesic properties, and tannic acid is not readily applicable on such a surface. Where skin toilet was not desirable it was the practice in this hospital to follow the first-aid dressing by the application of liquid paraffin or sterile vaseline, as continued application of picric acid had led to unpleasant results in cases of idiosyncrasy.

The application of cod-liver oil seemed so easy a method and so generally useful that it was decided to treat minor burns in an endeavour to estimate its value, and the comparison was very easy between tannic acid and the other oily dressings. It was soon decided that the use of cod-liver oil was quite justified, not only in burns of a minor degree, but also in those

of much greater extent and penetration. It has, in fact, been so successful that it is now almost a routine here to treat any burn with crude cod-liver oil. The main advantage is that, on admission, no matter what has been applied outside it is unnecessary to undertake any extensive skin toilet before applying dressings.

At first it was thought that cod-liver oil combined into an ointment with some waxy base would remain in closer contact with the burnt area, but it was soon found that the dressing, when the time came for renewal, was either dry or inclined to draw the granulated tissue away with the remains of the waxy ointment. To overcome this difficulty, lint, heavily soaked in cod-liver oil, was applied widely over the part to be treated, and was taken off at the end of 12 hours. With experience it has been found that once in 24 hours is sufficiently often to uncover the dressing, which is now left *in situ* and re-soaked with cod-liver oil, the lint not being taken from the skin surface until the end of 48 hours—an obvious advantage where the area to be treated is large.

Both Löhr and Winnett-Orr of Nebraska use the occlusive method, but the only occlusion that we have found necessary is to cover the dressing by jaconette, in an endeavour to keep the lint saturated. Crude cod-liver oil is used from the commencement in all cases. Where cases have not reacted previously to the ordinary dressings it has been found that cod-liver oil hastens recovery, and the speed with which an indolent area is transformed into one of healthy granulation is remarkable. The treatment too is popular. Almost every patient has said that the first application of cod-liver oil has given much greater ease than other dressings. One case, which is not illustrated, may be quoted.

A marine fireman, who was scarred in almost every part of his body, was burnt on the left arm, shoulder to elbow, whilst five days out from Liverpool, by a fall against the door of the ship's furnace. He sustained a burn of the third degree which was treated by picric acid on the boat, and on arrival at port he was sent to this hospital with all speed. He was in considerable pain and there was a good deal of toxicity from the picric-acid dressings. Cod-liver oil was immediately applied, and in 12 days he left the hospital with a completely healed surface and without any scars.

By a strange coincidence about 15 days later, on his return to port, he was sent into hospital by his panel doctor for an acute intestinal obstruction, and it was found that not only was there no scarring from the recent burns, but the brown pigmentation, which is so often left after this treatment, had entirely disappeared.

With our first few cases we obtained such good results in burns, that it was decided to try crude cod-liver oil as a dressing in other cases. Indolent ulcers and deep abrasions were so treated, but always following the rule 'if there is pus, it must be let out'. With this proviso cod-liver oil treatment has been found of advantage in a great number of slow-healing areas. After the removal of pus or gangrenous patches of skin, oil applied in the way described has induced rapid granulation of tissue previously indolent in leg ulcers and even in fistulae. One case of fistula had been in hospital 34 days under routine treatment and still showed a slight serous discharge. After packing the wound for six days with cod-liver oil the patient was able to leave hospital, and only needed to make two outpatient attendances for the renewal of the dry dressings.

Unless the distal and proximal surfaces of a joint are involved no immobilization is undertaken and no occlusion is attempted except that obtained by a covering of jaconette. Crude cod-liver oil is used and is applied by lint saturated therein. The dressing is not removed for 48 hours, but at the end of the first 24 hours—or more often if it seems necessary—it is re-soaked *in situ* with cod-liver oil. In certain cases at

the end of a week the granulations are found to be exuberant; cod-liver oil dressing is then replaced for 24 hours by red lotion or a paste with a zinc base.

The only disadvantage of the treatment, to which notice has been drawn, lies in the somewhat unpleasant smell from the dressing, but this can be mitigated by frequent change of bed linen. At one time we included an aromatic in the oil, but gave it up as it did not seem worth while. Sometimes the scent of the oil seems to make a patient less ready for his food, but this mild nausea soon passes away. The advantages are obvious: the ease which the patient obtains from the first dressing, the abolition of frequent change of dressings (with consequent pain and disturbance to the patient), and the almost total elimination of scar tissue. The brown pigmentation which is found on the healed skin clears up without further treatment.

A laboratory comparison was made between liquid paraffin and cod-liver oil, 10 c.cm. of either being inoculated with *Staph. pyogenes aureus*. In the case of cod-liver oil after 48 hours' incubation, subcultures on agar proved that although the organisms were still alive the growth was inhibited. The same result was obtained with liquid paraffin over a week. Obviously neither is a suitable medium for the growth of the organisms, and this will account for the change of an unhealthy surface into the 'clean ruddy picture of healing'.

Whether the vitamin content in cod-liver oil has a natural affinity for the skin and the underlying tissues it is difficult to say, but there is obviously some factor in cod-liver oil which is not present in such oily dressings as liquid paraffin. This 'something' has the effect of much more rapid healing and the almost entire elimination of scar tissue.

Reviews

LYON'S MEDICAL JURISPRUDENCE FOR INDIA: WITH ILLUSTRATIVE CASES.—By T. F. Owens, L.R.C.P. & S., Lieutenant-Colonel, I.M.S. (retd.). Ninth Edition. 1935. Thacker, Spink and Company (1933), Limited, Calcutta, and W. Thacker and Company, London. Pp. xvi plus 767. Illustrated. Price, Rs. 18

THE book has been recast and revised. Certain matters such as life assurance, not falling strictly within the scope of forensic medicine, have been omitted, while others such as the Medical Council for India and the provincial medical councils have been added. The size has been decreased by 75 pages. Yet, most of the familiar pictures are in their familiar places.

The myth of ptomaine poisoning has been cleared. Florence's test and Barberio test for seminal stain have been included.

One single item showing the least evidence of revision deals with blood groups. Doubts expressed regarding the determination of the group from blood-stains and regarding the determination of parentage from the groups of the alleged offspring and the alleged parents remain as strong as they were in the last edition. This is no longer the situation. Determination of the group from the stains either by the direct action of the isohæmagglutinin or by the absorption of the isohæmagglutinin is now well known. Bernstein's hypothesis of the inheritance of the blood groups is also well known. The irregular reaction in inheritance have been satisfactorily explained by the sub-groups A_1 and A_2 under A and by weakness of the hæmagglutinogens and the hæmagglutinins. 'As a matter of fact, a considerable number of "exceptions" to the Bernstein theory have been reported, but a comparison of the number of such cases before and after the theory was expounded reveals a remarkable decrease during the latter period. Thus, in the O × AB families, whereas

26.26 per cent of exceptions were found before 1926 only 3.61 per cent were found after that date. Similarly, in the A × AB families there has been a decrease from 3.77 per cent to 0.87 per cent in the number of exceptions; in the B × AB families the number of exceptions has dropped from 11.11 per cent to 0.83 per cent; and in the AB × AB families no exceptions were found at any time' (A. S. Wiener, 1934). Besides, the hæmagglutinogens M and N provide a check. Incidentally, the isohæmagglutinogens A₁ and A₂ and the hæmagglutinogens M and N have not been mentioned.

The preface by Colonel Waddell to the last (eighth) edition with two disputable claims is retained. In the new preface Colonel Owen has summarized lucidly the scope of the book without any strain on the superlatives.

The paper, the printing, the size and the binding are good. Inclusion of a plate, in colour, of the spectrum with the bands of the derivatives of hæmoglobin would be useful in the next edition.

The book will continue to enjoy, with added justification, the reputation it has already attained.

HANDBOOK OF PHYSIOLOGY.—By the late W. D. Halliburton, M.D., LL.D., F.R.C.P., F.R.S., and R. J. S. McDowall, M.B., D.Sc., F.R.C.P. (Edin.). Thirty-fourth Edition. 1935. John Murray, London. Pp. xi plus 971, with numerous illustrations in the text, many of which are coloured, and 4 coloured plates. Price, 18s.

THIS standard textbook has now reached its thirty-fourth edition and can, in spite of its age, be said to be modern in every respect. The editor is to be congratulated on presenting the subject of physiology in so concise and yet comprehensive a volume. A complete critique of the whole book is impossible and indeed unnecessary, and a comment on certain topics and chapters has been selected on account of some new features which have been incorporated.

The autonomic nervous system has been ably handled in a few pages and the recent work on humoral transmission cholinergic and adrenergic fibres incorporated. The cardiovascular system has justifiably been given a more exhaustive treatment and the student should be able to appreciate the information which modern laboratory methods, namely the oscillograph, has yielded in the elucidation of the nature of the nerve impulse and hence the function (among others) of the cardiac nerves.

The respiratory system includes all the most recent work on the subject and shows the effect on respiratory activity of an artificial embolus. Such innovations are of the nature of experimental pathology and should be of considerable value to the thoughtful student when he meets such conditions in the wards. The book is eminently suited to the average medical student and yet provides material for the more intelligent ones who realize the importance of a sound understanding of physiological facts and principles in the interpretation of symptoms at the bedside. The undergraduate would be well advised to keep this book by his side throughout the latter part of his medical curriculum.

H. E. C. W.

PUERPERAL GYNÆCOLOGY.—By J. L. Bubis, M.D., F.A.C.S. 1935. Baillière, Tindall and Cox, London. Pp. xxiii plus 199, with 81 illustrations. Price, 16s.

It must be acknowledged that a large number of pregnant women suffer pathologically, as the result of what is actually a physiological process.

It is a matter for regret that a natural process such as labour should leave in its train—cystoceles, rectoceles, prolapses, chronic infections of the cervix, and innumerable other troublesome complications. The duty of the doctor is to obviate these complications and to return the mother to her home as fit as before she became pregnant. Gynæcological statistics indicate that this ideal is seldom reached.

For 18 years, Dr. Bubis has been advocating the immediate repair of injuries to the birth canal. It seems incredible that he should have to do so—but it is equally incredible that few doctors ever examine the birth canal after delivery. Dr. Bubis has broken new ground by writing a book of 180 pages—divided into 18 sections, the first three of which are devoted to anatomy, pre-natal care and delivery, the latter containing an excellent résumé of anæsthesia and analgesia for labour cases. Four sections are devoted to puerperal and gynæcological operations. Two sections devoted to 'puerperal care following delivery and repair' and special therapy are particularly worthy of note.

The book is profusely and clearly illustrated; abundant statistics are given to prove the authors' contentions. Many would object to carry out complete repairs after delivery. Whatever criticisms may be advanced, few will deny the author's statement that 'the slightest laceration is worthy of attention'.

The book should be in the hands of all medical men and women practising midwifery. It contains much food for thought and even if half the author's recommendations are acted upon, the mother will be benefited.

S. N. H.

UROLOGY IN GENERAL PRACTICE.—By A. E. Roche, M.A., M.D., M.Ch. (Camb.), F.R.C.S. (Eng.). 1935. H. K. Lewis and Company Limited, London. Pp. xii plus 355, with 3 coloured plates and 40 figures. Price, 17s. 6d.

THAT a sound working knowledge of urology in general practice is not only of increasing importance, but an absolute necessity, is emphasized by the great number of books on this subject that have made their appearance in recent years.

Mr. Roche has added to the literature on urology an excellent little book, written in a free and easy style, and containing many quips of a humorous nature. It is definitely intended for the general practitioner, and should prove of great use to him. The volume is divided into ten parts, the first two being concerned with the investigation of a urological case and urinary symptoms. The next seven describe pathological conditions under regional headings, such as kidney, prostate, etc. Embryology is not described, and no condition is dealt with at length, which is in keeping with a book of this size.

The section on tuberculosis of the kidney occupies only two pages, but torsion of the spermatic cord, and of the hydatid of Morgagni are dealt with fully.

In describing catheterization of the bladder and ureters, and also cystoscopy, the author insists on the very true dictum, that gentleness is the keynote of success, and he gives many useful suggestions to be borne in mind when performing any of these examinations.

All the sections are well written and contain those essentials which are necessary for the general practitioner. The tenth part is a short synopsis of recent advances in urological treatment. The illustrations consist of skiagrams and photographs, and there are three coloured plates.

H. E. M.

MANUAL OF HUMAN PHYSIOLOGY.—By Sir Leonard Hill, M.B., LL.D., F.R.S.Hon.A.R.I.A. Fourth Edition. 1935. Edward Arnold and Company, London. Pp. xii plus 470. Illustrated. Price, 6s. 6d.

THE fourth edition of Sir Leonard Hill's excellent *Manual of Human Physiology* brings this work fully up to date. The whole text has been thoroughly revised so as to keep pace with the recent advances. The inclusion of the chapter on reproduction has made the book complete. Being an essentially elementary book, it must include some of the simpler facts of anatomy for the proper elucidation of the subject to

beginners. Such subjects as are of general interest have been laid stress on, while all unimportant details have been excluded. The book is designed for the higher classes of schools and polytechnics, and for nurses undergoing hospital training and one can confidently recommend it to these.

R. N. C.

THE PHARMACOLOGICAL ACTION OF HARROGATE DRINKING WATERS.—By W. Bain, M.D. (Dunelm), F.R.C.P. (Lond.), F.R.C.S. (Edin.). 1935. J. and A. Churchill Limited, London. Pp. vii plus 53, with 26 illustrations. Price, 5s.

THE publication of this book is timely, for there is no work of this kind available and it will help to put spa treatment on a rational and scientific basis. The author has endeavoured to investigate the Harrogate drinking waters from a pharmacological point of view. Of the eighty-eight different springs, complete analysis has been made of only fourteen which are used for drinking purposes. In the different chapters the author deals with the action of the water on the gastro-intestinal tract, biliary passage and cardiovascular system. The text is well illustrated with graphs that are very instructive. The book will be of interest to all medical practitioners and especially to those making use of spa treatment.

R. N. C.

THE SNAKES OF INDIA.—By Lieut.-Col. K. G. Gharpurey, B.A., F.R.G.S., F.Z.S., I.M.S. 1935. The Popular Book Depot, Lamington Road, Grant Road, Bombay. Pp. x plus 165. Illustrated. Price, Rs. 3

A SMALL but a comprehensive book dealing with Indian snakes written in very simple and non-technical language fit for general practitioners and laymen was urgently required. We have always felt the necessity of some book to which to refer people, as we have had

to reply to many enquiries regarding the identification, classification and treatment of snake bites.

This volume is an excellent attempt to fulfil all these requirements. It gives briefly, in simple and concise language, the general description of the important snakes of India with the salient features regarding their classification and identification. Seventy-six illustrations and diagrams are given to illustrate the different types of snakes. Five pages have been allotted to the first treatment of snake bite. Special stress has been laid on the fact that out of 300 important Indian snakes only 40 are poisonous and out of these the majority are cobras. Hence out of every 5 cases of snake bite only one is by a poisonous snake, but out of every 100 cases bitten 90 cases survive without any treatment. This exposition should give great encouragement to victims, who are so frequently subject to great shock through fear alone.

We strongly recommend this book to students and practitioners and people in out of the way places, such as forest offices, military offices, factories and plantations.

OTHER BOOKS RECEIVED

Facts and Fallacies of Practical Birth Control—including an Examination of the 'Natural Method' of Contraception of the Gräfenberg Ring, and of Sterilization. By G. R. Scott, F.R.A.I., F.P.H.S. (Eng.), F.Z.S. Published by Messrs. T. Werner Laurie Limited, London (Cobham House, 24 and 26, Water Lane, E.C. 4). Pp. ix plus 156. Illustrated. Price, 5s.

Leprosy: With Special Reference to its Occurrence in India. By S. N. Malhotra, M.B., B.S. (Pun.), F.C.P.S. (Bom.), M.D. (Voll.). 1935. Published by The Rayan Pharmacy (Publishers), 97, Girgaum Road, Bombay. Pp. 110. Price, Rs. 4-4

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1933. VOLUME I. ON THE STATE OF THE PUBLIC HEALTH IN BRITISH INDIA AND SOME INDIAN STATES

1. THE chief vital statistical facts relating to British India for 1933 are:—

(1) Total births numbered 9,678,876 giving a crude birth rate of 35.5 per mille as compared with 33.7 in 1932.

(2) Total deaths numbered 6,096,787 giving a crude death rate of 22.4 per mille as compared with 21.6 in 1932.

(3) Infantile deaths numbered 1,650,973, or 27 per cent of the total mortality, giving an infantile death rate per 1,000-births of 170.5 as compared with 168.7 in 1932.

(4) The crude increase in population was 3,582,089 which gives a rate of 13.1 per mille.

In these four short paragraphs are summarized the main health statistics of India for 1933 and they may conveniently be made the text for the introductory paragraph of this annual review.

In the first place it is clear that there has been no violent disturbance in the Indian vital statistical world. The birth rate, though somewhat higher than in the two previous years, has merely returned to the average level recorded during the 33 years of the present century and the slight reductions recorded during 1931 and 1932 seem to have been merely fortuitous in character and cannot be taken to indicate that there is any tendency for the Indian peoples to follow the example of western nations in

respect of restriction of families. The death rate is slightly higher than that recorded in 1932 but does not show any great departure from the downward trend which has characterized the general death rate since the great influenza epidemic of 1918-19. Unfortunately, the same cannot be said of the infantile death rate. In the 1931 report attention was drawn to the downward trend in this rate following the disastrous years of 1918 and 1919 but the recorded rates of the past 6 years seem to indicate that that trend has disappeared. Since 1928, in fact, the annual figures for infant mortality have fluctuated only slightly between 181 per 1,000 births in 1930 and 169 in 1932 and the figure for 1933 again lies between these two contiguous limits. It seems that, for the present, the factors influencing infantile mortality are comparatively stable and that new and more vigorous preventive measures will have to be planned and put into execution before a further saving of infant life can be expected. No public health officer can look with any degree of equanimity on an annual death roll of nearly 1½ million infants below one year of age and if, as has been repeatedly stated, the infant mortality rates of a nation provide an accurate estimate of its sanitary conditions then India has little cause for satisfaction as regards the state of its public health. The further deduction may be made that existing campaigns in the fields of child welfare and maternity relief have had so far little or no widespread influence, although no doubt in the restricted areas in which they are carried on a considerable effect may have been produced. As a matter of fact the small degree to which this form of preventive work has so far developed makes it evident that the merest fringe of the problem has been touched and it could

not possibly have produced effects sufficiently profound to have influenced the infantile death rates common to the general population of rural India. In any case, these facts and figures indicate the enormous problems awaiting attack and make clear the extent of the health work facing the new provincial and central Governments which will shortly come into being under the reformed constitution.

The three main epidemic diseases, cholera, plague and smallpox, together caused 214,590 deaths but although this number is somewhat higher than in the previous year, owing to an increased prevalence of smallpox, the combined death rate was only 0.9 per mille. Cholera was for another year only a minor problem, and although it is dangerous to be optimistic, it seems unlikely that India will in the future suffer the devastating pandemics which were a feature of the later years of the 19th century. Plague once more shows a reduced incidence and although the total deaths still numbered nearly 43,000, in this case also, the disease appears to be gradually dying out. Smallpox deaths increased in a disconcerting manner from 45,000 in 1932 to 103,000 in the year under review and the epidemic was fairly widespread over the whole of the Indian peninsula. The present exacerbation after a series of years of comparative freedom from epidemic smallpox indicates how far India still has to go before this disease is satisfactorily controlled.

Of the 3½ million deaths registered as due to 'fevers', probably a large proportion were actually caused by malaria. It is also a fair assumption that numbers of malaria deaths were recorded under 'other causes'. Remembering also that 12½ million diagnosed cases of malaria attended at hospitals and dispensaries, it may be fairly estimated that during 1933 malaria exacted a toll of at least 1,000,000 lives. This terrible mortality is apt to be lost sight of owing to the defective and misleading nature of statistical records and because of the less dramatic nature of the disease as compared with cholera, plague and smallpox, except when a violent epidemic occurs such as that of 1908 in the Punjab. But year after year in India, malaria is probably responsible for about 20 per cent of the total recorded deaths and many millions of the population experience periods of sickness which cause grave loss of earning power and much economic distress. The problems associated with the prevention of malaria in this vast sub-continent are such as might well daunt the most courageous, for the poverty of the people and the lack of resources among local boards and municipalities prohibit all expensive measures. During recent years a number of local governments have made successful attempts in certain particularly malarious areas to provide the stricken populations with free supplies of quinine and, even although here also lack of funds has restricted effort, a considerable degree of betterment has been achieved. In a later section of this report an attempt has been made to estimate the amounts of quinine distributed through hospitals and dispensaries and by public health staffs in the different provinces and a brief examination of the figures will show how ludicrously inadequate these quantities are. At the same time, under present circumstances, probably more benefit can be conferred by the distribution of quinine than by other anti-malarial measures and it is to be hoped that the Government of India will be able to accept the suggestion that its reserve stocks of quinine should be gifted to the provinces in order that, even temporarily, more adequate supplies of the drug may reach the people. It is an unfortunate fact that India cannot herself produce anything like the amount of quinine her population requires and that present prices make it largely a prohibitive luxury to most of her people. Nevertheless it is urgently important that larger quantities should be made available, for it is difficult to suggest other means of succour to the millions who suffer from this deadly disease.

At the risk of being accused of vain reiteration, it seems once more necessary to invite attention to the increasing gravity of the problems associated with the

continued growth of the population which still proceeds apace. During 1933, the population of British India increased by over 3½ millions, and the estimated population at the mid-year period was nearly 273 millions. There is no reason to think that in the Indian States the same increase has not occurred, for these States are in such intimate relationship with different parts of British India, that any factor tending to reduce numbers in one, would exert a similar force in the other. This means that since the end of February 1931, nearly 18 millions have been added to the population of India and on a conservative estimate the total must now be approximately 370 millions. This estimate is almost certainly conservative because, for the purposes of these calculations, the rate of increase has been taken as that recorded during the decade 1921-31. This rate has, however, been considerably exceeded each year since the census of 1931 so that it would not be unduly stressing the case to add another 2 millions to the grand total. Even with this omission, however, the problem is large enough and if existing conditions continue—and at the moment of writing no indication of change is evident—there seems little doubt that by 1941, when the next census is taken, the population of India will considerably exceed the estimate of 400 millions given in last year's report. The population problem in India is therefore a real one and because scepticism still exists in the minds of certain authorities who continue to ignore facts, that problem demands further examination from an angle which, so far as I am aware, has not yet been given sufficient attention. The late Mr. Joseph Chamberlain, at one stage of his political career, spoke of 'three acres and a cow' as providing a sufficient standard of living for the average English agricultural labourer and this famous phrase has been frequently used since as forming a suitable basis on which to found arguments intended to defeat *laissez faire* opposition. Examination of the figures in India gives interesting results. The total land in British India amounts to 667 million acres but of this total only 232 million acres were cultivated and sown, 47 millions lying fallow, 154 millions being culturable but uncultivated, 145 millions being not available and 89 million acres consisting of forests. Even making the ridiculous assumption that the whole 667 million acres of land were available, this works out at only 2.44 acres per head of the population. A more reasonable assumption would be to take the acreage made up of cultivated and sown, fallow, and culturable but uncultivated. These three items total 481 million acres which gives only 1.75 acres per head of the population. But some land must be allowed to lie fallow, an additional proportion must be given over to the cultivation of crops other than food and, during 1933-34, the total acreage under food crops amounted to only 206½ million acres. This gives only 0.72 acre per head of the population in British India and it does not require more than an elementary knowledge of agriculture to realize that it is impossible to provide a sufficiency of food for the present population of India from an acreage of this dimension. It may even be held that were all available cultivable land given over to food production alone, the supply would fall short of reasonable and adequate demand. In order to forestall the usual argument, it can be admitted that the present shortage *might* be met for a short period of years by more intensive methods of cultivation, but that implies the immediate adoption of these intensive methods all over India and to those of us who know the village *ryot*, it is difficult to envisage a solution of the problem along those lines. Even supposing that additional food supplies were made available in this way, however, the difficulties would only be postponed for a few years, because the increased numbers of the population would rapidly absorb the surplus. Apparently, therefore, the problem of numbers in India is even more acute than before and it is one of such importance to the welfare of this country that it deserves immediate examination and certainly more detailed notice than it receives in paragraphs of this

report. Numbers are so intimately bound up with economics that the problem is one which affects every department of Government and every class of citizen. It is a question which will shortly force itself upon the attention of every man and woman in this country: it is hoped that it will receive adequate notice before disaster befalls.

SECTION II

History of chief diseases

Chief causes of mortality.—The 'fevers' group, no doubt including most of the deaths in which fever was a notable symptom of the fatal illness, is once more the largest and comprises nearly 58 per cent of the total deaths with a death rate of 12.9 per mensem. Deaths recorded under 'other causes' seem to remain fairly constant as the percentage to the total, viz, 27 per cent, and the death rate of 6.1 per mensem are both much the same as last year. The respiratory diseases group comprises 7 per cent of the total and gives a death rate of 1.6 per mensem, both figures also being similar to those of 1933. The only deaths which are registered with a reasonable standard of accuracy are those from cholera, plague and smallpox, but even in these instances the absence of death certification makes the recorded figures somewhat incomplete and unreliable. Deaths from true cholera are frequently registered as 'diarrhoea' and deaths from dysentery and diarrhoea as frequently find their way into the cholera category; smallpox deaths are recorded as measles and chicken pox and *vice versa*, whilst, owing to the ignorance and carelessness of those responsible for registration, cases in which fever has been a marked feature of the illness are buried under the omnibus term 'fevers'. As regards 'other causes' a large proportion of these deaths in Burma were ascribed to debility and anaemia, circulatory, urinary and digestive diseases; in the Central Provinces 3,457 deaths followed child-birth, 2,452 were due to measles and chicken pox and the remaining 105,631 to causes 'for which there is no separate column in the vital statistics form or which the reporting agency was unable to classify'. In other provinces similar conditions prevail. The methods in vogue detract greatly from the epidemiological value of the recorded statistics and little improvement can be expected until suitable registration agencies are constituted. Generally speaking, this will be a difficult problem for many years to come, but there are nevertheless a number of minor improvements which could be introduced without much delay, difficulty or expense. These include (1) the compulsory certification of causes of deaths in urban areas; (2) the adoption in prescribed areas of the International 'short' list of causes of death and (3) a uniform extension of the present list of notifiable diseases. Valiant efforts have been made in certain provinces during recent years to verify at least a proportion of the recorded deaths and, as might have been anticipated, wide variations have been obtained between the figures returned by the ordinary and the verifying agencies. At the same time, until some system of this kind is generally adopted, the statistics of mortality in India dealt with in this section must remain mere approximations and can only be used for analytical purposes with considerable reserve.

With the transfer of 'public health' in 1919 to local Governments the onus of initiative in improving registration has lain on provincial health departments and whilst in certain provinces considerable and successful efforts have been made in this direction, generally throughout India the results achieved have been so far disappointing.

Cholera.—During 1932 and 1933 the incidence of cholera was the lowest recorded in India during the last 60 years. In the former year, the long-wave cholera cycle was at its minimum and it was anticipated that 1933 would record an increase. This increase duly occurred though it was slight and most of the cholera was confined to the western districts of the Central Provinces, to the eastern districts of Bombay Presidency and to Hyderabad State, with an exacerbation

in Assam. Total recorded deaths numbered 68,318 as against 67,219 in 1932 and these figures compare very favourably with that of 354,438 which is the mean for the 5-year period of 1928-32. Throughout the 57-year period from 1877 to 1933, for which reliable records are available, only in 12 years have recorded deaths been fewer than 200,000; in the other 45 years cholera has regularly been the cause of a very high mortality, the deaths varying between 217,000 in 1893 and nearly 800,000 in 1900.

In the form of a concentrated picture of past and present events the recorded cholera deaths by quinquennial periods from 1877 onwards are given below:—

Period	Total deaths	Annual average
1877-81	1,468,487	293,697
1882-86	1,457,114	291,423
1887-91	2,030,020	406,004
1892-96	2,243,590	448,718
1897-01	1,942,016	388,403
1902-06	1,862,132	372,426
1907-11	2,023,514	404,703
1912-16	1,675,833	335,167
1917-21	1,986,978	397,396
1922-26	742,184	148,437
1927-31	1,509,680	301,936
1932	67,219	67,219
1933	68,318	68,318

These figures show that the violently explosive outbreaks of earlier years are now less frequent. This feature reflects credit on the publicity and preventive campaigns launched by provincial public health departments, the Indian Red Cross and other voluntary associations. Although every province still ordinarily shows its own seasonal curve, it is satisfactory to note that all have shared in the general decline.

Judging from the provisional data now available, the cholera wave has continued to rise during 1934, so that the usual cycle seems to be in course of development. At the same time, no very severe epidemic is anticipated; the large decline in incidence during recent years, as compared with the high peaks recorded during the last decade of the 19th century and the early years of the present century, suggests that certain new factors have been at work throughout the country in reducing the severity of this endemic disease. Whilst, therefore, the long-wave cycle is still in evidence and an increased incidence is likely to be recorded during the next two to three years, there is every hope that the cholera mortality figures will not reach undue dimensions. This hope is born of the knowledge that preventive work during recent years has been peculiarly successful in all the larger *melas* and religious gatherings, where millions of pilgrims are wont to attend. Almost without exception public health departments have reported a complete absence of cholera during and after these gatherings which were formerly such hotbeds of infection, and this alone must have the most profound influence on the incidence of the disease over wide tracts of the country. Another factor of importance is the increasing use of anti-cholera vaccine which is now well known to give a high degree of protection. The continued cheapness of food grains and the prevention of anything approaching famine conditions are additional factors favouring the reduction and control of cholera outbreaks. Speaking generally, therefore, it seems unlikely that in the future India will ever again suffer so severely from this disease as it has done in the past, although this will of course depend on continued vigilance on the part of every public health department and on immediate action when outbreaks occur. Whilst some cause for optimism exists, however, there is nothing in the present situation which can permit of any relaxation on the part of the public health officers; rather does it require renewed effort in order that India may eventually become free of this dreaded scourge.

Anti-cholera measures.—Routine sanitary measures such as improvement of water supplied in villages and

Bombay Presidency.—Preliminary experiments were carried out at the Haffkine Institute by Lieutenant-Colonel S. S. Sokhey, I.M.S., in artificial 16 feet long zig-zag burrows covered with plate glass sealed down with mud. Rats in perforated metal cylinders and fleas in muslin bags were placed at different points in the burrows and free rats were also introduced; cyanogas dust was then pumped in. This experiment, repeated several times, showed that rats and fleas up to a distance of 16 feet were invariably killed.

Similar experiments in natural burrows found in a dilapidated roofless house in Poona city indicated that 96 per cent of the rats present were killed. Encouraged by these results, Bijapur town, where plague had only been absent one year since 1924, was selected for a trial. Out of 2,400 pounds of the dust supplied to the municipality, 1,644 pounds were actually used. The freedom of the town in 1934 was attributed to the use of cyanogas dust but, to confirm the results, it is proposed to extend the operations to a selected group of villages. In one house in Bijapur town, all rats and fleas were destroyed, not only in the three rooms directly fumigated but those in the fourth room having free communication with one of these rooms. In another room, which was shut off from the fumigated rooms by a small door, about half of the rats escaped and 10 dead rats and a dead lizard were found to have fallen from the roof. In another part of the same town, where grain godowns are situated, 503 houses containing 2,233 rat burrows were fumigated and here even the rats and snakes that left the burrows died after a short time.

In addition, 5,300 pounds of cyanogas dust were supplied to 16 other local bodies in British districts and Indian States, but the results obtained are not yet known.

Punjab.—With a view to the adoption of cyanogas for the destruction of rats and fleas in infected areas in lieu of, or as an auxiliary to, *bhoosa-battis*, preliminary experiments were conducted with cyanogas dust 'A' both in artificial and natural rat holes, in the fields as well as in houses. It was found that the minimum period of exposure to the gas required was 2 minutes. The following conclusions were recorded:—

(i) Experiments carried out with *bhoosa-battis* in the Punjab Epidemiological Bureau in 1926 indicated that the lethal range of the smoke did not extend beyond 10 feet for the rats and 5 feet for the rat fleas. On the other hand, with cyanogas the range of destruction for both rats and rat fleas has been found to extend to a distance of 15 feet from the mouth of the rat hole.

(ii) About one in eight of the *bhoosa-battis* were extinguished soon after the rat holes were closed with mud and consequently failed to destroy the inmates. There is no such difficulty in the case of cyanogas.

(iii) *Bhoosa-battis* are harmless to human beings but cyanogas with a low diffusive power should not be a source of danger if it is handled by a competent staff. Moreover if doors are left open, only a small concentration of the gas is retained in the air of the room and within 2 hours after the house is opened up only slight traces of the gas are left.

Burma.—Fumigation with cyanogas was begun in October 1934, and so far outfits have been obtained by 37 municipalities, 19 district councils and 7 other institutions and 1,265 pounds of the fumigant have been purchased. It is not possible to give definite results as yet but the degree of success has apparently varied in different localities. In the town of Mandalay, this new method of killing rats and their fleas has been a pronounced success, plague deaths having totalled only 14 during the last plague season as against an average mortality of 739.

Smallpox.—During 1933, over a quarter of a million cases of smallpox were recorded with nearly 104,000 deaths. These figures are the highest for several years past and, considered apart from the influence of preventive measures, indicate that like the other great epidemic diseases of India smallpox continues to adhere

to a long-wave cycle which has a fairly regular periodicity. In Bihar and Orissa which had severe epidemics during 1925 to 1927, the present cyclic increase was anticipated a year in advance and the Director of Public Health explains the increased mortality in the following words:—

'It is a known fact that vaccination prevents and limits outbreaks of smallpox, but still the rate of mortality from this cause tends to show sharp rises at times in this province. This is due to the fact that a large number of children escape even primary vaccination and thus remain unprotected. Besides, the immunity conferred by vaccination gradually declines with the passage of time, with the result that protection passes off within 6 to 7 years'.

This explanation seems applicable to other parts of India as the 1933 epidemic was widespread and of the total recorded deaths, 16,936, or over 16 per cent, occurred amongst infants and 27,390, or over 26 per cent, amongst children between 1 and 10 years. But there were exceptions and it is probable that these areas which escaped during 1933 will record epidemic outbreaks during 1934 and 1935.

With the exceptions of the Central Provinces and the two outlying provinces of Assam and Burma, every province reported a higher incidence and in Delhi, Bihar and Orissa and Ajmer-Merwara the increases were marked. In Delhi province, over 90 per cent of the smallpox deaths occurred among children under 10 years of age, which fact certainly reveals defects in revaccination work; probably the same may be said of Ajmer-Merwara. The North-West Frontier Province and the Punjab were less severely infected but in the former the death rate was 7 times the quinquennial mean and in the latter it was nearly double that mean. The Presidencies of Madras and Bengal each recorded twice the number of deaths registered during the previous year and Bombay Presidency had almost three times as many as in 1932. These are decidedly disquieting figures, even taking into account the cyclic periodicity of the disease and it is to be hoped they have acted as a spur to the health departments concerned in their preventive efforts. They should also have provided due warning to provinces like the Central Provinces and Assam which have so far escaped from the present epidemic, for the portents are that these areas will later suffer unless active steps have been taken to push both vaccinations and revaccinations.

It may be of advantage to individual health officers and others to note here some of the more apparent factors which go to discount preventive campaigns against smallpox in this country. Even where notification is compulsory it is not properly enforced; the loss of time involved inevitably postpones adoption of preventive measures which require prompt application if isolated outbreaks are not to assume epidemic proportions. On the other hand, where early notification has been made, outbreaks have been quickly and successfully controlled. Again, large numbers of children remain unprotected because of defective registration of births and because in nearly all rural areas and even in many urban areas vaccination has not been made compulsory. The first of these handicaps has been reduced considerably during recent years and it is to be hoped will soon disappear. The second is a matter which should be the concern of every officer engaged in public health work and can only be removed by patient and continued educational activities. Again, revaccination is not compulsory except in a few centres and as a result many individuals are never vaccinated after infancy. The acceptance of this preventive measure can only be achieved by propaganda suited to the populations which it is meant to influence. Lastly, isolation of smallpox cases is hardly ever practised because there are few infectious diseases hospitals in existence and because, even if there were, existing legislation is very defective and public opinion is non-existent as to the desirability of isolation. These are

at *melas*, etc.; improvement of conservancy, medical inspection at railway stations of pilgrims, and the employment of epidemic staffs were adopted in various centres as and when necessary.

Inoculation with the anti-cholera vaccine is now generally accepted in India as a preventive method of proved efficacy. Whilst in some few endemic areas a proportion of the population has reached the stage of asking for inoculation on the approach of the cholera season, unfortunately it is ordinarily resorted to only after an outbreak has occurred or when an epidemic threatens to break out. But even then it has its valued place in preventive campaigns and in most areas the people are willing to submit themselves to inoculation as they are well aware of the protection it confers. With the growth of district health organizations and especially where whole-time health officers are employed, it is now much more easy to bring this preventive method to the average villager and in the absence of other more permanent measures, anti-cholera inoculation will for long continue to be one of the most valuable weapons in the hands of public health staffs. Further records have been collected in order to demonstrate the varying incidence of the disease amongst inoculated and non-inoculated groups.

Plague.—The upward trend in the mortality curve recorded in the preceding two years was not maintained, the total deaths in 1933 decreasing to 42,631. The reduction in incidence was particularly marked in Northern India where plague has long been endemic. Provisional figures for the early months of 1934 indicate, however, that the comparative calm of the last 5 years in this endemic focus is likely to be disturbed by an outbreak of moderate intensity. During 1933, the most important plague focus in North-East India, which includes the foot-hills of the Himalayas in the eastern United Provinces and western Bihar, reported only mild or sporadic infection; although in the upper Ganges Valley infection was somewhat severe. In the Punjab, a mild epidemic continued to be reported in the sub-montane tracts. The increased mortality in the Peninsula and especially that in Bombay Presidency was the only real disquieting feature. In Bombay Presidency the epidemic curve, after reaching its annual peak in December 1932, declined steadily during the first five months of 1933, but thereafter took an upward trend reaching its maximum in October and the total plague deaths in this area were the highest since 1924. The most heavily infected districts were Bijapur, Belgaum, Dharwar, Satara and Sholapur in the Southern Registration District—in which area the disease persists in endemic form—and Poona in the Central Registration District. These areas accounted for over 97 per cent of the provincial total. The most noteworthy feature of plague during 1933 therefore was its continued persistence in its old haunts. In the Central Provinces, although mortality was generally low, the districts of Chhindwara and Hoshangabad in the Machadeo Hills again suffered worst. In the Madras Presidency, Bellary district recorded 61 per cent of the provincial total. North-West Frontier Province, Delhi and Ajmer-Merwara remained free as did the whole eastern seaboard of India, northern Burma, Assam, Bengal, the south-east parts of Bihar and Orissa and the western areas of the Punjab and upper Sind.

Burma.—Plague is generally a disease of the cold weather in this province and during 1933 the highest mortality was recorded in January, February, March of the year. The total of 972 deaths compares very fact that India's annual average of 4,826; in fact amount of quinine per mensem was the lowest present prices make action of the disease in 1905. most of her people. Whilst trapping and poisoning important that larger part in a well-organized able, for it is difficult to just plague, these measures to the millions who are infected rat-flea which in At the risk of being an important factor in spreading seems once more necessary recent years more and increasing gravity of

more attention has been paid to the life history of rat-fleas and to the epidemiological features which favour their breeding; an obvious corollary to investigations in those directions is experimentation devised to discover the most suitable methods for destruction of these insects by disinfestation of rat burrows which afford the main harbourage both for rats and fleas. With this end in view, experiments have been carried out in several centres during the past year or two with various preparations which contain a considerable proportion of HCN. Generally, the results obtained have been very encouraging and it appears likely that by means of one or other of the HCN products now on the market, the development of plague can be largely controlled, provided suitable apparatus and methods are adopted. A brief summary of the experiments carried out in Madras, Bombay, the Punjab and Burma is here recorded; this should be of direct interest to public health officers who have to deal with plague-infected areas.

Madras-Cumbum Valley.—Epidemic plague has been in existence in Cumbum village from 1926 onwards. In March 1932, an attempt was made to fumigate every rat burrow in every house of this village, no less than 11,948 burrows in 2,210 houses out of a total of 3,334 being treated. While the burrows were being inspected prior to fumigation, dead rats were occasionally found and a few of these showed signs of plague infection. The 1932 outbreak in and around the Cumbum Valley was fairly severe, a total of 2,014 cases and 701 deaths being recorded. Eighty-seven cases of human plague occurred in the village itself in the latter half of 1931, 30 in January, 9 in February and 4 in March 1932, when fumigation was begun. No further plague occurred until January 1933 (3 cases) and February (7 cases) and none thereafter until February 1934. Every attempt was made to obtain the earliest information of rat falls or human plague and as soon as a plague-infected rat was discovered, the house concerned and the adjacent houses were again fumigated. In all 110,000 burrows were treated and whilst the number of animals dying inside the burrows could not be ascertained, 3,150 dead rats were found outside the burrows and, in addition, 1,156 mice, 232 bandicoots, 11 field rats, 9 musk-rats and a number of snakes, frogs and lizards were picked up dead. In six localities fumigation was carried out after rat falls were discovered and no further rat falls and no human plague cases were detected. Twenty localities were fumigated at times when human cases were occurring there almost daily and the outbreaks appeared to be checked. Four localities which were fumigated towards the end of the 1932 epidemic remained entirely free during 1933 and a further 6 localities were apparently protected from plague by fumigations carried out after neighbouring villages were heavily infected. In only 2 villages were the results disappointing. The work done in this area appears to furnish strongly suggestive evidence that fumigation with cyanogas is of considerable value in the prevention of plague. Further experiments carried out during 1934-35 have shown that where fumigation is carried out sufficiently early, the epizootic is promptly aborted. Villages which were fumigated when infection threatened either completely escaped or the onset of the outbreak was considerably delayed. During this period a further 184,000 rat burrows were treated in and around 16,000 houses in 25 different localities and thousands of rats, mice and bandicoots were killed.

In view of these encouraging results, the use of cyanogas was extended to the plague-infected villages of Bellary district and with a grant from Government towards the cost of pumps and cyanogas powder, fumigation of rat burrows during the plague off-season was proposed. As a result of the field researches in this direction, a revised memorandum on plague preventive policy has been prepared and submitted to the Madras Government for their approval. This memorandum includes a note on the technique of cyanogas fumigation and the precautions to be adopted.

Bombay Presidency.—Preliminary experiments were carried out at the Haffkine Institute by Lieutenant-Colonel S. S. Sokhey, I.M.S., in artificial 16 feet long zig-zag burrows covered with plate glass sealed down with mud. Rats in perforated metal cylinders and fleas in muslin bags were placed at different points in the burrows and free rats were also introduced; cyanogas dust was then pumped in. This experiment, repeated several times, showed that rats and fleas up to a distance of 16 feet were invariably killed.

Similar experiments in natural burrows found in a dilapidated roofless house in Poona city indicated that 96 per cent of the rats present were killed. Encouraged by these results, Bijapur town, where plague had only been absent one year since 1924, was selected for a trial. Out of 2,400 pounds of the dust supplied to the municipality, 1,644 pounds were actually used. The freedom of the town in 1934 was attributed to the use of cyanogas dust but, to confirm the results, it is proposed to extend the operations to a selected group of villages. In one house in Bijapur town, all rats and fleas were destroyed, not only in the three rooms directly fumigated but those in the fourth room having free communication with one of these rooms. In another room, which was shut off from the fumigated rooms by a small door, about half of the rats escaped and 10 dead rats and a dead lizard were found to have fallen from the roof. In another part of the same town, where grain godowns are situated, 503 houses containing 2,233 rat burrows were fumigated and here even the rats and snakes that left the burrows died after a short time.

In addition, 5,300 pounds of cyanogas dust were supplied to 16 other local bodies in British districts and Indian States, but the results obtained are not yet known.

Punjab.—With a view to the adoption of cyanogas for the destruction of rats and fleas in infected areas in lieu of, or as an auxiliary to, *bhoosa-battis*, preliminary experiments were conducted with cyanogas dust 'A' both in artificial and natural rat holes, in the fields as well as in houses. It was found that the minimum period of exposure to the gas required was 2 minutes. The following conclusions were recorded:—

(i) Experiments carried out with *bhoosa-battis* in the Punjab Epidemiological Bureau in 1926 indicated that the lethal range of the smoke did not extend beyond 10 feet for the rats and 5 feet for the rat fleas. On the other hand, with cyanogas the range of destruction for both rats and rat fleas has been found to extend to a distance of 15 feet from the mouth of the rat hole.

(ii) About one in eight of the *bhoosa-battis* were extinguished soon after the rat holes were closed with mud and consequently failed to destroy the inmates. There is no such difficulty in the case of cyanogas.

(iii) *Bhoosa-battis* are harmless to human beings but cyanogas with a low diffusive power should not be a source of danger if it is handled by a competent staff. Moreover if doors are left open, only a small concentration of the gas is retained in the air of the room and within 2 hours after the house is opened up only slight traces of the gas are left.

Burma.—Fumigation with cyanogas was begun in October 1934, and so far outfits have been obtained by 37 municipalities, 19 district councils and 7 other institutions and 1,265 pounds of the fumigant have been purchased. It is not possible to give definite results as yet but the degree of success has apparently varied in different localities. In the town of Mandalay, this new method of killing rats and their fleas has been a pronounced success, plague deaths having totalled only 14 during the last plague season as against an average mortality of 739.

Smallpox.—During 1933, over a quarter of a million cases of smallpox were recorded with nearly 104,000 deaths. These figures are the highest for several years past and, considered apart from the influence of preventive measures, indicate that like the other great epidemic diseases of India smallpox continues to adhere

to a long-wave cycle which has a fairly regular periodicity. In Bihar and Orissa which had severe epidemics during 1925 to 1927, the present cyclic increase was anticipated a year in advance and the Director of Public Health explains the increased mortality in the following words:—

'It is a known fact that vaccination prevents and limits outbreaks of smallpox, but still the rate of mortality from this cause tends to show sharp rises at times in this province. This is due to the fact that a large number of children escape even primary vaccination and thus remain unprotected. Besides, the immunity conferred by vaccination gradually declines with the passage of time, with the result that protection passes off within 6 to 7 years'.

This explanation seems applicable to other parts of India as the 1933 epidemic was widespread and of the total recorded deaths, 16,936, or over 16 per cent, occurred amongst infants and 27,390, or over 26 per cent, amongst children between 1 and 10 years. But there were exceptions and it is probable that these areas which escaped during 1933 will record epidemic outbreaks during 1934 and 1935.

With the exceptions of the Central Provinces and the two outlying provinces of Assam and Burma, every province reported a higher incidence and in Delhi, Bihar and Orissa and Ajmer-Merwara the increases were marked. In Delhi province, over 90 per cent of the smallpox deaths occurred among children under 10 years of age, which fact certainly reveals defects in revaccination work; probably the same may be said of Ajmer-Merwara. The North-West Frontier Province and the Punjab were less severely infected but in the former the death rate was 7 times the quinquennial mean and in the latter it was nearly double that mean. The Presidencies of Madras and Bengal each recorded twice the number of deaths registered during the previous year and Bombay Presidency had almost three times as many as in 1932. These are decidedly disquieting figures, even taking into account the cyclic periodicity of the disease and it is to be hoped they have acted as a spur to the health departments concerned in their preventive efforts. They should also have provided due warning to provinces like the Central Provinces and Assam which have so far escaped from the present epidemic, for the portents are that these areas will later suffer unless active steps have been taken to push both vaccinations and revaccinations.

It may be of advantage to individual health officers and others to note here some of the more apparent factors which go to discount preventive campaigns against smallpox in this country. Even where notification is compulsory it is not properly enforced; the loss of time involved inevitably postpones adoption of preventive measures which require prompt application if isolated outbreaks are not to assume epidemic proportions. On the other hand, where early notification has been made, outbreaks have been quickly and successfully controlled. Again, large numbers of children remain unprotected because of defective registration of births and because in nearly all rural areas and even in many urban areas vaccination has not been made compulsory. The first of these handicaps has been reduced considerably during recent years and it is to be hoped will soon disappear. The second is a matter which should be the concern of every officer engaged in public health work and can only be removed by patient and continued educational activities. Again, revaccination is not compulsory except in a few centres and as a result many individuals are never vaccinated after infancy. The acceptance of this preventive measure can only be achieved by propaganda suited to the populations which it is meant to influence. Lastly, isolation of smallpox cases is hardly ever practised because there are few infectious diseases hospitals in existence and because, even if there were, existing legislation is very defective and public opinion is non-existent as to the desirability of isolation. These are

all severe handicaps to those engaged in the campaign against smallpox, but all are capable of reduction if the health officers concerned constantly keep them in mind and use every available opportunity to rouse the public conscience. It may be admitted at once that this task is a difficult one: it is however not impossible as the progress already made in certain provinces during the past decade has shown.

[This report which is the most important one we receive is much too long to abstract completely in a single issue of the *Gazette*, so it is proposed to continue it in the next issue.]

REPORT ON THE PUBLIC HEALTH AND SANITARY ADMINISTRATION OF THE CITY OF RANGOON FOR THE YEAR 1934

THE death rate of the year (23.66) was slightly higher than that (22.11) of 1933 but lower than the quinquennial mean (25.93) and the mean of the last decade (29.92).

The number of deaths from smallpox (75) was higher than that (14) of the previous year but lower than the average (190) of the last ten years. Four deaths were registered from cholera as against 5 in 1933, the average number of deaths for the last ten years being 61. Plague accounted for 27 deaths as compared with 9 deaths in the previous year and 198 average deaths during the last ten years. There were 4 deaths from cerebro-spinal meningitis as compared with 1 during 1933. The average number of deaths from this disease during the last ten years was 8.

The number of typhus fever cases reported during the year was 8 without any deaths as against 1 case reported during 1933. In the past such cases were missed and diagnosed as typhoid, paratyphoid and pyrexias of uncertain origin, but, owing to the more frequent use of the laboratory for purposes of diagnosis, the existence of this fever is being detected now.

Eighty-three deaths were attributed to beri-beri which caused 75 deaths in the previous year, the average number of deaths during the last ten years being 84.

This disease was mostly confined to people of the labouring classes who were either unemployed or had uncertain incomes owing to the depressed state of the various trades and industries.

Five hundred and eight deaths were due to diarrhoea and dysentery which caused 458 deaths in 1933, the average number of deaths during the last ten years being 914. The areas most commonly affected were those that had inadequate water supply and were unsewered. The necessity of piped water supply in adequate quantities and the extension of the sewerage system in such areas is only too evident.

Enteric fever accounted for 46 deaths as compared with 52 in 1933. The average number of deaths during the last ten years was 65.

The number of deaths from tuberculosis was 831 as against 817 in 1933, the average of the last ten years being 923. During the last five years 3,760 deaths occurred from pulmonary tuberculosis as against 4,734 of the previous five years. There is, however, no doubt of the fact that the mortality from this disease is a very disquieting feature, in the state of the public health of the city.

The infantile mortality rate (270.81) although higher than that of the last year (257.03) was lower than the quinquennial mean (283.27). The loss of more than one-fourth of the infants born in the town before they even attain the age of a year can never be looked upon as satisfactory in any community and requires the concerted activities of all—not only of those charged with the improvement of the public health of the city but of all social workers. With a view to reducing the high rate of infantile mortality prevailing at present, the system of work under the maternity and child welfare scheme has been overhauled and the number of health visitors raised from 6 to 15. It is hoped that the newly-started health school will increase the supply of trained persons available for this work. Four thousand and twenty-three or 41.10 per cent of the total confinements were still attended by unqualified women and the need for the free provision of midwives in the outlying parts of the town where poor people live is very great.

Service Notes

APPOINTMENTS AND TRANSFERS

BREVET-COLONEL H. H. THORBURN, C.I.E., is appointed to officiate as Inspector-General, Civil Hospitals and Prisons, North-West Frontier Province, with effect from the 30th September, 1935 (afternoon), *vice* Colonel C. I. Brierley, C.I.E., granted leave preparatory to retirement.

The services of Lieutenant-Colonel G. H. Mahony are placed temporarily at the disposal of the Government of Bihar and Orissa, with effect from the 9th October, 1935.

Lieutenant-Colonel R. F. D. MacGregor, M.C., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Hyderabad, with effect from the forenoon of the 19th October, 1935.

Lieutenant-Colonel C. Newcomb, Principal and Professor, Medical College, Madras, is appointed to officiate as Surgeon-General with the Government of Madras, with effect from the 29th October, 1935 (afternoon), *vice* Major-General Sir Frank P. Connor, Kt., D.S.O., appointed to officiate as Director-General, Indian Medical Service.

Lieutenant-Colonel C. A. Godson made over charge of the Hooghly Jail to Major J. C. Drummond on the afternoon of the 14th November, 1935.

The services of Major F. R. W. K. Allen are placed permanently at the disposal of the Government of the Central Provinces, with effect from the 17th May, 1935.

Major J. J. Rooney, an Agency Surgeon, on return from leave, resumed charge of his appointment of Residency Surgeon, Bushire, with effect from the forenoon of the 18th October, 1935.

Major J. S. Galvin, on relief, to be Civil Surgeon, Belgaum, pending further orders, *vice* Rao Bahadur V. B. Gokhale.

Major H. Williamson, O.B.E., an Agency Surgeon, is posted as Civil Surgeon, Sibi and Loralai, with effect from the forenoon of the 29th October, 1935.

The services of Major J. R. Katariya, formerly Superintendent, Presidency Jail, are replaced at the disposal of the Government of India, Army Department, for military duty, with effect from the 1st September, 1935.

This cancels previous notification.

Captain H. S. Waters to be Presidency Surgeon, Bombay, with attached duties on his reversion from the Government of India, *vice* Major J. S. Galvin.

Captain B. S. Sandhu is appointed to act as Superintendent of the Presidency Jail, with effect from the 1st September, 1935, *vice* Major J. R. Katariya reverted to the Military Department.

This cancels previous notification.

LEAVE

Lieutenant-Colonel W. P. Hogg, D.S.O., M.C., an Agency Surgeon, is granted 7 months' leave, with effect from the afternoon of the 11th September, 1935.

Major S. L. Patney, Superintendent, Dacca Central Jail, is allowed leave for 8 months, with effect from the 2nd December, 1935, or any subsequent date on which he may be relieved.

PROMOTIONS

Lieutenant-Colonels to be Colonels

C. E. Palmer. Dated 15th February, 1935, with seniority 1st March, 1929.

W. J. Powell, C.I.E. Dated 14th August, 1935, with seniority 1st March, 1929.

Majors to be Lieutenant-Colonels

R. A. Logan. Dated 1st October, 1935.

F. M. Kirwan. Dated 11th October, 1935.

R. C. Phelps. Dated 28th October, 1935.

Captain to be Major

R. A. Wesson. Dated 30th October, 1935.

Captains to be Majors (provisional)

K. S. Fitch. Dated 13th October, 1935.

S. C. H. Worseldine. Dated 14th October, 1935.

RETIREMENT

Lieutenant-Colonel C. A. Godson, M.C. Dated 15th November, 1935.

RELINQUISHMENT OF TEMPORARY COMMISSIONS

Captain L. D. Sarronwala. Dated 1st September, 1935.

Captain M. N. Pai. Dated 16th September, 1935.

Captain T. R. R. Pai. Dated 26th September, 1935.

Notes

ARTIFICIAL LIMBS

Loss of a limb is a much more serious thing in this country than in many European countries, as not only has the cost of the artificial limb to be considered, but hitherto the difficulty of getting one that fits properly has constituted an almost insuperable problem.

There is properly no artificial leg made anywhere in the world that has such an established reputation as the Desoutter leg. The manufacturers have overcome the difficulty of supplying this limb to residents in far countries, such as India, by preparing a most elaborate, but apparently completely fool-proof, chart for taking exact measurements of the stump and normal leg, to ensure correct fitting.

We have personal knowledge of more than one Desoutter artificial leg that has been in use for many years in Bengal; these limbs have stood up very well against this extremely trying climate, so that no fears need be entertained on this account.

On the general use of these limbs we give an extract from the *Lancet* that we hope may interest readers:—

A new artificial leg for above-knee amputations has been demonstrated to us by a wearer of the appliance. The limb is the invention of Mr. Charles Desoutter, of the firm of Desoutter Bros., and appears to mark a real advance in prosthetics. A new system of construction has been used, the limb being made from seamless pressings solid-drawn from a flat sheet of 'alclad', a trade name for duralumin coated with pure aluminium. The shin from the knee to the ankle is of one piece, and the thigh from the knee to the crutch also consists of one seamless pressing, and the result is an apparatus which combines strength with remarkable lightness. The limb only weighs $3\frac{1}{2}$ to 4 lb.

To the orthopaedist the point of greatest interest is the knee-mechanism, which so controls the swinging speed and action of the joint as to make the walking natural. The loose and pendulous swing, which is a notable feature of a heavy artificial limb, was absent from the gait of the one-legged man who paraded before us; he was an above-knee amputee with a stump approximately $9\frac{1}{2}$ inches long. The half bending jerky knee action typical of the knee control of many of the artificial limbs that found their way on the market after the war was entirely absent.

A notched control wheel is sunk flush in the knee and is easily rotated with slight thumb pressure through the clothing. The shape and natural appearance of the appliance are due to the absence of outside straps and elastics, the pelvic band affording sufficient support. The wearer during the demonstration first walked with the knee control out of action, when the artificial nature of his limb was obvious; but on turning the control wheel his gait became natural, when he said that he

could now walk much faster. The easy action has been arrived at by mounting the wheel on a minute ball-bearing thrust race. The spring is a sort of artificial quadriceps, and the action gradually weakens as the leg flexes, becoming neutral in the sitting position.

A film in slow motion prepared by the firm shows well the leg action of a normal person walking, and discloses that in taking a step forward with natural gait the leg starts its bend and swing comparatively slowly, not rising high from the ground. But in coming forward acceleration occurs until the step is complete. In this film two men are shown walking side by side, one of whom has two legs, while the other has lost a leg above the knee. It needs an expert eye to discern any difference.

Medical men may obtain literature charts, etc., post free on application to the office of this journal.

LIVER PREPARATIONS

Livogen

It is at the present time the 'fashion' to prescribe liver for almost any condition in which anæmia is a prominent feature, and for many in which it is not. Though we deprecate the indiscriminate prescribing of liver, nevertheless we have to admit that in few conditions does it do any harm and in a great variety of conditions it is of real value, whether by virtue of its iron content, its high protein value, its vitamin content, or the presence of the specific hæmopoietic factor.

A very attractive liver preparation is put up by British Drug Houses, Limited, in the form of Livogen. This preparation not only contains liver extract with all its numerous hæmopoietic and nutritional factors, but in addition a concentrated extract of yeast with its associated vitamin B (complex), and additional iron in the form of hæmoglobin.

This preparation should be of great value when liver is prescribed for conditions other than those in which the specific hæmopoietic factor only is required, that is to say, for 99 per cent of the conditions for which liver is usually prescribed in this country.

Livader

This is a concentrated liquid extract of liver which is guaranteed to conform with the specification for *extractum hepatis liquidum* B. P. 1932; it contains the whole of those effective anti-anæmic principles of liver the administration of which causes a rise in the percentage of reticulocytes and the restoration of the blood picture to normal in persons suffering from pernicious anæmia and from other anæmias associated with megaloblastic hyperplasia of the bone marrow.

One fluid ounce (about 30 c.cm.)—an average daily dose—contains the whole of the hæmopoietic principles of half a pound of fresh liver.

Livadex is administered orally; it may be taken by the spoonful, or it may be sipped undiluted from a wineglass. If desired it may be diluted with its own volume of hot or cold water, but usually it is found to be more palatable undiluted.

The usual daily requirement is one fluid ounce, or two tablespoonfuls, until the normal blood picture is restored, after which time a maintenance dose of one tablespoonful daily is generally sufficient.

Liver Extract B. D. H.

Liver Extract B. D. H. (for intramuscular injection) contains the anti-anæmic principles of liver free from protein; it is in such a state of purity that its injection—intramuscularly or intravenously—produces a quick response without serious depressor effects or other objectionable sequelæ. It is remarkably active, 1 c.cm. containing the pernicious anemia fraction obtained from 35 to 50 grammes of fresh liver.

The intramuscular injection of liver extract is at least thirty times as effective as the oral administration of an equal quantity of extract. Two cubic centimetres of Liver Extract B. D. H., parenterally administered, therefore, is equivalent in effect to the oral administration of over 500 grammes of fresh liver; its injection daily produces a satisfactory response within three or four days, by which time the patient usually is recovered sufficiently to revert to oral treatment with Livadex, if desired. The injection of an appropriate dose at regular intervals, or of a larger dose at more extended intervals, will ensure the continuance of normality.

JAIL FOR SALE OF SPURIOUS DRUG

'I feel that the public need to be protected from such heartless exploitation of the sick and the injured'. With this remark Mr. Oscar H. Brown, Presidency Magistrate, Bombay, passed a sentence of one month's rigorous imprisonment and a fine of Rs. 250 on an employee of a stationery firm, on a charge of selling a spurious 'Antiphlogistine'.

'The accused', the Magistrate further commented, 'exploited a well-known drug which is largely used by the medical profession and known even by laymen simply by the name. In cases of dangerous illness incalculable harm may be done by the use of a drug which is not as efficacious as the one prescribed by a doctor'.

In default of fine the accused was ordered to undergo further imprisonment for three months.

THE MODERN ANTISEPTIC

'DETTOL' is now available to doctors in India.

This antiseptic has become widely adopted by hospitals and doctors throughout the United Kingdom although it was introduced only 2½ years ago. The reason for this is not far to seek.

The government report on maternal mortality and morbidity in 1932 stated that the antiseptics then in use left a great deal to be desired and apart from 2 per cent aqueous iodine nothing could be relied upon to effect complete destruction of hæmolytic streptococci on the skin, and to remain an effective germicide when dried.

Soon afterwards, Messrs. Reckitt and Sons, Limited of Hull introduced 'Dettol' and subsequent research at the Bernhard Baron Research Laboratories showed that undiluted Dettol, like 2 per cent aqueous iodine, was able completely to destroy hæmolytic streptococci on

the hands, and to render them insusceptible to reinfection by hæmolytic streptococci for at least two hours afterwards; unlike iodine, however, Dettol was clean in use and painless in application besides being pleasant smelling. Also a 2 per cent solution of Dettol was able to kill hæmolytic streptococci in two minutes in a 50 per cent solution of pus and blood—a definite advance on iodine which, being unstable in the presence of blood and pus, was suitable only for simple skin sterilization. Dettol was, therefore, particularly suitable for general cleaning as well.

The full report appeared in *The Journal of Obstetrics and Gynaecology of the British Empire* (XX, 966), and further details were given during a speech at the British Medical Association Meeting in Dublin.

In *Queen Charlotte's Quarterly* for February 1935 it is now shown that consequent upon the introduction of Dettol into the labour wards there was a sharp drop in the sepsis rate. Reports of reductions elsewhere, even on a considerable scale, are being received by the manufacturers.

Dettol is three times as effective a germicide as pure carbolic acid (Rideal-Walker test), and being non-corrosive and non-toxic it can be used at highly effective concentrations. These qualities, in addition to its stability, render it of particular value in wound treatment and general surgical applications.

Dettol is now available in India, as it has been placed on the market through Messrs. Atlantis (East), Limited, 20/21, Chetla Road, Calcutta.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

BACTERIOPHAGE IN THE TREATMENT OF CHOLERA

By C. L. PASRICHA, M.A., M.B., B.Chir., M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

Professor of Bacteriology and Pathology
A. J. H. DE MONTE, I.M.D.

Officer-in-Charge, Bowel Disease Research Department
and

E. G. O'FLYNN, D.T.M. (Cal.), I.M.D.

Research Worker under the Indian Research Fund Association

(An enquiry at the School of Tropical Medicine, Calcutta, financed by the Indian Research Fund Association)

BACTERIOPHAGE is an agent that has already been used extensively, in both the prophylaxis and treatment of certain bacterial infections and there is every indication that its use is being considerably extended. Not only is bacteriophage popular with the medical profession who advocate it on account of the ease of its administration, but in many cases patients swallow the contents of bacteriophage ampoules on their own initiative without any medical advice.

There is a general impression that here at last is an agent that can be safely administered, that is harmless to the tissues of the host, and that can destroy bacteria and in doing so reproduces itself a millionfold. The idea is so attractive and so exceedingly simple; added to this, are the emphatic claims made by d'Herelle for bacteriophage as a natural agent in the cure of disease and a most valuable therapeutic agent in the hands of the physician. With bacteriophage, d'Herelle claims to have treated successfully cases of cholera, dysentery, and plague, and in the field to have controlled and stamped out epidemics of these diseases.

A voluminous literature has grown up on the practical application of bacteriophage. This literature contains reports and records of experiments and trials. Except for the reports of d'Herelle and his followers, almost all of which claim uniformly successful results, many of these are both disappointing and contradictory. It is necessary, therefore, that, in a country such as India where diseases exist in which, if we accept d'Herelle's contentions, bacteriophage is the ideal method of treatment, we should examine very critically the results obtained in the use of bacteriophage.

In this present communication we shall confine ourselves to the use of bacteriophage in the treatment of cholera.

A review of the literature of the use of bacteriophage in the treatment of cholera reveals that the evidence is for the most part contradictory. d'Herelle, Malone and Lahiri

(1930) reported dramatic success in the treatment of cholera with bacteriophage. These workers recorded a mortality of 8.1 per cent amongst bacteriophage-treated cases (74 cases) as compared with a mortality of 62.9 per cent in untreated cases (124 cases). Further, analysis of the value of bacteriophage according to the time of administration after the onset of symptoms showed that, when bacteriophage is administered within six hours of the onset of symptoms, there was no mortality (26 cases), that, when the administration of bacteriophage was between six to 24 hours, the mortality was 10.2 per cent (41 cases), and that in seven cases in which bacteriophage was administered after more than 24 hours there was a mortality of 14.3 per cent. These workers also stressed the importance of its administration by mouth only, and said that bacteriophage must never be given to the patient by the subcutaneous route. These experiments were carried out under primitive conditions in villages, and the amount of bacteriophage employed in the majority of instances was 6 c.cm. per case.

Morison and Vardon (1929) reported the results of a small outbreak of cholera in which they treated 31 cases with bacteriophage with a mortality of 29 per cent, as compared with a mortality of 75.8 per cent amongst 29 cases receiving no bacteriophage. More recently, Morison, Rice and Choudhury (1934) analysed in detail the results obtained by them in their experiments with bacteriophage in the field extending over a number of years. These trials were also carried out under primitive village conditions and the majority of cases received only 2 c.cm. of bacteriophage by the mouth. Under the conditions of the experiment which was spread over a number of villages, these workers found it impossible to maintain alternate case controls. They made exhaustive and detailed comparisons as regards age, sex, caste and the period in the epidemic in which the cases occurred, and found that amongst 1,007 cases of cholera studied in the field in two epidemics, 364 phage-treated cases had a mortality of approximately 50 per cent of that of the untreated cases.

Of other favourable reports of the value of bacteriophage as a therapeutic agent under field conditions, mention may be made of the extensive trials of Asheshov (1931 and 1932) and the Director of Public Health, Bihar and Orissa (1933, 1934 and 1935).

King (1934) also reported favourable results in the treatment of a small series of cases. This investigator stresses the difficulty in comparing the phaged cases with unphaged cases in the mass owing to the greater attention being paid in the collection of data from the phaged area than from the control non-phaged area. He also draws attention to the enthusiasm in officers and health inspectors as an important factor which may influence the collection of figures.

Although the many reports of good results from the use of bacteriophage in the treatment of cholera under field conditions make it difficult to assert that bacteriophage is without effect in treatment of the disease, it is still more difficult in the absence of adequate controls to arrive at an unequivocal verdict in favour of the therapeutic value of bacteriophage.

Of the reported trials of bacteriophage therapy in any extensive series of cholera cases under hospital conditions, we are aware of only four experiments. Ross, Bagchi and Roy (1928) report the results of treatment in hospital of 16 cases with choleraeophage of which only two died as against three deaths out of seven treated otherwise. The authors claimed no statistical validity for the results.

Taylor, Greval and Thant (1930) using a bacteriophage of high activity observed a mortality of 57 per cent in 14 treated cases of bacteriologically-proven cholera compared to a mortality of 53 per cent in a series of 19 similar cases not treated with bacteriophage. Alternate cases were treated. The stools were examined for the presence of bacteriophage and in the great majority of cases in which recoveries occurred these workers found no evidence of bacteriophage in the stools active against the patients' own vibrios. These investigators concluded that bacteriophage is not an essential agent of recovery and that its administration was not an effective therapeutic measure in the class of case dealt with.

This was the first serious report against the therapeutic use of choleraeophage. In this connection reference might also be made to Souchard (1930) who attempted to confirm the work of d'Herelle. This author used a bacteriophage supplied by d'Herelle, prepared it in the same way and administered it in doses recommended by d'Herelle but failed to obtain similar results. The mortality in a group of 27 treated cases was 87 per cent, only three recoveries being obtained. This mortality was identical with the prevailing mortality in untreated cases at the same time in the same locality.

Asheshov, Khan and Lahiri (1930 and 1931) treated 266 cases of cholera in the cholera wards of the Patna Medical College Hospital and obtained a gross mortality of 7 per cent in 140 bacteriologically-proven cholera cases. These workers had no parallel series of control cases and give as control figures the mortality rate in the same hospital before the introduction of bacteriophage. These control figures were 21 per cent gross mortality and 25 per cent in the bacteriologically-proven cases. The bacteriophage was given undiluted in about one-drachm doses every half hour for the first 16 hours and later a bottle containing 50 c.cm. of phage was given daily for two days. For more rapid action, these workers advocated the use of bacteriophage intravenously in 5 c.cm. doses, considerably diluted and best administered along

with the salt solution. There was considerable selection of cases in the phage-treated series, and the control non-phaged series of only 24 cases was in a different period of the epidemic, so that, when it is remembered that the mortality in cholera varies very considerably in different periods of the epidemic, much of the value of the arguments advanced is lost.

Harvey (1933) gives an excellent review of the literature on choleraeophage, and, after a critical survey of the published reports dealing with the practical application of choleraeophage, concludes:—'Bacteriophage prophylaxis and therapy have made greater advances in cholera than in plague. Much of the work with both these diseases, however, is confusing, contradictory and uncontrolled, whilst failure of prophylactic or therapeutic action of the bacteriophage is apt to be accompanied by an *apologia* that is complicated and not convincing. We may hope that the trials in cholera at present progressing will afford the evidence of complete and permanent suppression of its epidemic character. None the less we are of opinion that proof of favourable action, unless dramatic and continued, is most likely to be obtained by the comparison of cases alternately treated with and without phage. In view of the conflicting opinions which are prevalent regarding the living virus-nature of the bacteriophage, the only judgment, which seems to us possible on this question, is one of non-proven'.

In 1933, we (Pasricha, 1934) carried out an experiment to evaluate bacteriophage in the treatment of cholera. Two wards were set apart in the Campbell Hospital for cholera cases, and the admission of cases was alternately into the two wards. The treatment in the two wards was identical except that in one bacteriophage was used in addition to the usual treatment of cholera. Bacteriophage used was constantly 'refreshed' by passage with vibrios isolated during the different phases of the epidemic and was given mainly by the mouth. In 50 cases choleraeophage was given intravenously and gave us satisfactory results. A very brief summary of the results of this experiment is abstracted from the *Annual Report of the School of Tropical Medicine*, 1933.

TABLE I

The number of clinical cases of cholera treated with choleraeophage and number not treated with choleraeophage with the total deaths in the two series

	Treated with choleraeophage	Not treated with choleraeophage
Total number of clinical cases of cholera investigated.	290	180
Number of deaths irrespective of cause.	42 or 14.5%	40 or 22.2%

TABLE II
Summary of the bacteriological findings of the two series with the number of deaths in the different groups of cases

	TREATED WITH CHOLERAPHAGE (TOTAL 290)		NOT TREATED WITH CHOLERA- PHAGE (TOTAL 180)	
	Total number	Deaths	Total number	Deaths
1. Number of cases in which agglutinating vibrios (either alone or together with non-agglutinating vibrios) were isolated.	170	18 or 10.6%	103	20 or 19.4%
2. Number of cases in which non-agglutinating vibrios only were isolated.	33	3 or 9.1%	9	1 or 11.1%
3. Number of cases in which no vibrios were isolated.	87	21 or 24.1%	68	19 or 28.0%

The results obtained corroborate to a certain extent the evidence deduced by other workers on the value of cholera-phage in the treatment of cholera, but are neither as dramatic nor as convincing as some of the earlier recorded results.

The present experiment

This experiment might be considered as a continuation of the experiment in 1933. The experience gained then, when we studied 470 cases of cholera in the course of two months during the height of the cholera epidemic, was invaluable in planning the present enquiry. It was realized that for an intelligent application of bacteriophage therapy, a close co-operation between the clinician and the laboratory was essential and for this purpose one of us (E. G. O'F.) was made personally responsible for the collection of specimens from patients, the administration of bacteriophage, and the collection of data.

During the year ending 30th July, 1935, 1,369 cases admitted into the cholera wards of the Campbell Hospital were investigated. Of these 684 were treated with cholera-phage and 685 were not treated with cholera-phage. The selection in the two series was made by taking alternate admissions into the wards, irrespective of age, severities and general condition of the patient. Both series received the usual hospital routine treatment for cholera, the phage-treated cases received in addition cholera-phage in doses of 2 c.cm. every four hours. Except for the period 1st April, 1935 to 31st May, 1935, during the height of the cholera epidemic when two wards were available for cholera cases, the experiment was conducted in one ward.

The usual hospital treatment is so well known that it is not necessary to give details of it here. The only medication given by the mouth was in the form of divided doses of calomel. In order to determine whether these doses of calomel had any deleterious effects on bacteriophage administered by the mouth, we examined the stools of a number of cases and found no significant difference between those that had and had not taken calomel. Every case was

examined bacteriologically on the day of admission, or, if admitted during the night, the next morning. Later, examinations were made at least once in every 24 hours, up to the complete disappearance of symptoms and when possible a certain number of cases were followed up after discharge from hospital. Special efforts were made to examine repeatedly those cases clinically cholera but bacteriologically negative. Specimens from patients were collected in the majority of cases with the aid of our special catheter outfits, so as to ensure freedom from any extraneous contamination. In addition to the direct plating by the bed-side, the peptone water enrichment method was also employed.

Cholera-phage used for treatment was prepared on freshly-isolated agglutinable strains. It was realized that uncontrolled and haphazard application of stock bacteriophage prepared on one set of vibrios could not be expected to yield any conclusive results. Our therapeutic cholera-phage was therefore constantly 'refreshed' on recently-isolated vibrios. Freshly-isolated potent phages were frequently added to the 'seed phages' and every effort was made to

TABLE III
Analysis of the 1,369 cases of cholera studied during the year ending 30th July, 1935. The number of cases clinically cholera, treated and not treated with bacteriophage, and the gross mortality in the two series irrespective of cause of death

	Treated with cholera-phage	Not treated with cholera-phage
Total number of cases clinically cholera.	684	685
Total number of deaths irrespective of the actual cause of death.	92	114
Percentage mortality	13.5	16.6

ensure the presence of a larger number of types of cholera-phage in each brew. This last often necessitated the addition of some of the types separately. The results have been analysed, and a brief summary of the bacteriological findings of the cases treated and not treated with cholera-phage, and the mortality in the two series is given in tabular form.

TABLE IIIa

Analysis of cases admitted to the cholera wards of the Campbell Hospital from the 1st April, 1935 to the 31st May, 1935, when there were separate phage and non-phage wards

Number of cases clinically cholera, treated and not treated with bacteriophage, and the gross mortality in the two series irrespective of cause of death.

	Treated with cholera-phage	Not treated with cholera-phage
Total number of cases studied	209	220
Total number of deaths irrespective of cause of death.	34	53
Percentage mortality ..	16.2	24.1

The only criterion of the results of treatment employed in these and subsequent tables has been recovery or death. Whether the patient was admitted dying or died within a few hours, or whether death occurred from other causes than cholera has not been taken into consideration. We have not excluded a single case. All cases are taken as cholera and all deaths as due to cholera. There is no selection of cases.

When we examine the results we find that the gross mortality is less, though not statistically significant, in the phage-treated series. Further, that the difference in the mortality rates between the phage-treated and control series is more marked during the period when the phage-treated cases were in a separate ward. There is suggestive evidence to support d'Herelle's opinion that therapeutic bacteriophage administered to a patient in a ward rapidly spreads throughout the ward. In fact d'Herelle expressed the opinion that no crucial experiment as to the efficacy of bacteriophage could be carried out except in places where arrangements could be made to isolate rigidly every case so as to prevent the spread of phages from one case to the other. Such experimental conditions would be difficult to obtain in India and it would be difficult to deal with a large number of cases.

It will also be noted that the mortality in both the phage-treated and control series is higher in the second group. This is undoubtedly due to the increased mortality rate at the height of the epidemic.

When we group the cases according to the results of bacteriological findings we observe significant differences in the mortality in the phage-treated and control series.

TABLE IV

Analysis of the total number of cases in whom vibrios (agglutinable or inagglutinable) were isolated and the mortality in the phage-treated and control series

	Treated with cholera-phage	Not treated with cholera-phage
Number of cases passing vibrios.	398	443
Percentage of vibrio-positive cases.	58.2	64.7
Number of cases passing vibrios that died irrespective of the actual cause of death.	33	79
Percentage mortality ..	8.3	17.8

TABLE IVa

Analysis of the number of cases (during the period of separate phage and non-phage wards) in whom vibrios (agglutinable or inagglutinable) were isolated and the mortality in the phage-treated and control series

	Treated with cholera-phage	Not treated with cholera-phage
Number of cases passing vibrios.	150	166
Percentage of vibrio-positive cases.	71.8	75.5
Number of cases passing vibrios that died irrespective of the cause of death.	15	37
Percentage mortality ..	10	22.3

The difference in the percentage mortality in the phage-treated and non-phage-treated series is more marked and is statistically significant in both group of figures. It can be reasonably held that cases in which we were not able to find any vibrios were also cholera, but this does not, we think, vitiate the significance of these figures. No attempt has been made to select cases and the same care and attention was paid in the examination of both series of cases. It will be noted that, whereas in the total number of cases we found vibrios in 60 to 65 per cent of the cases, in the cases during the height of the epidemic the number of cases in which

vibrios were found was 72 to 76 per cent. The actual number of cases in which vibrios were found are large enough to justify the statistical conclusions.

We can reasonably conclude that in cases of clinical cholera in which we were able to isolate

vibrios, bacteriophage is of definite therapeutic value. If we analyse this group of cases passing vibrios according to the types of vibrios isolated, we obtain a still better contrast between the phage-treated and the control series.

TABLE V

The total series

The frequency of agglutinable and inagglutinable vibrios in the bacteriophage-treated and control series, together with the number and percentage of deaths in each group.

Type of case	TREATED WITH CHOLERAPHAGE			NOT TREATED WITH CHOLERAPHAGE		
	Cases	Deaths	Percentage, mortality	Cases	Deaths	Percentage, mortality
Total number of cases in whom vibrios were isolated.	398	33	8.3	443	79	17.8
Total number of cases in whom only agglutinable vibrios were isolated.	219	15	6.8	244	49	20.1
Total number of cases in whom both agglutinable and inagglutinable vibrios were isolated.	118	13	11.0	125	27	21.6
Total number of cases in whom agglutinable vibrios were isolated either alone or together with inagglutinable vibrios.	337	28	8.3	369	76	20.6
Total number of cases in whom only inagglutinable vibrios were isolated.	61	5	8.2	74	3	4.7

TABLE Va

The series of cases treated in separate phage and non-phage wards during the height of the epidemic

The frequency of agglutinable and inagglutinable vibrios in the bacteriophage-treated and control series together with the number and percentage of deaths in each group.

Type of case	TREATED WITH CHOLERAPHAGE			NOT TREATED WITH CHOLERAPHAGE		
	Cases	Deaths	Percentage, mortality	Cases	Deaths	Percentage, mortality
Total number of cases in whom vibrios were isolated.	150	15	10.0	166	37	22.3
Total number of cases in whom agglutinable vibrios only were isolated.	83	4	4.8	74	19	25.7
Total number of cases in whom agglutinable and inagglutinable vibrios were isolated.	51	8	15.7	66	15	22.7
Total number of cases in whom agglutinable vibrios were isolated either alone or together with inagglutinable vibrios.	134	12	9.0	140	34	24.3
Total number of cases in whom inagglutinable vibrios only were isolated.	16	3	18.8	26	3	11.5

Of the total number of 398 cases of cholera passing vibrios in the phage-treated series we found agglutinable vibrios in 337 cases or approximately 85 per cent of the vibrio passers. The mortality in this group is 8.3 per cent. Of the 443 cases in the non-phage series 369 cases or 83 per cent of the vibrio passers were found to pass agglutinable vibrios. The mortality in this group is 20.6 per cent. The results in this group are statistically significantly different.

In the smaller group of cases admitted during the height of the epidemic, we have a mortality of 9 per cent in the phage-treated cases passing agglutinable vibrios, either alone or together with inagglutinable vibrios, as compared to a mortality of 24.3 per cent in the non-phage series. In those cases in which we isolated agglutinable vibrios only, the difference in the rates of mortality is even more marked, 4.8 per cent in the phage-treated series and 25.7 per cent in the non-phage series.

There is one group of cases in which phage apparently gave unfavourable results. These

are the cases in which, in spite of repeated search, we found only inagglutinable vibrios, the mortality in the phage-treated series (61 cases) being 8.2 per cent as compared with 4.7 per cent in the control series (74 cases). No satisfactory explanation can be advanced for this failure and apparent harmful effect of phage therapy as judged by the mortality rates alone. The actual number of cases are far too small to lead to any definite conclusions and the figures are not statistically significant. It must be remembered however that the cholera phage used in the experiment had been propagated on agglutinable vibrios only. The effect of bacteriophage prepared on inagglutinable vibrios, or a therapeutic phage prepared on both agglutinable and inagglutinable vibrios of a particular epidemic, still remains to be determined.

Finally, there remain a group of cases in both the phage-treated and control series in which we failed to isolate any vibrios or in which no examinations were made. The results in these groups are summarized below :—

TABLE VI

I. Total series

Number of cases in which no vibrios were isolated or in which no examinations were made and the mortality in the phage-treated and control series.

	TREATED WITH CHOLERAPHAGE			NOT TREATED WITH CHOLERAPHAGE		
	Cases	Deaths	Percentage, mortality	Cases	Deaths	Percentage, mortality
Total number of cases in whom no vibrios were isolated.	234	20	8.5	194	6	3.1
* Total number of cases not examined.	52	39	75.0	48	29	60.4

TABLE VIa

II. The series of cases treated in separate phage and non-phage wards during the height of the epidemic

Number of cases in which no vibrios were isolated or in which no examinations were made and the mortality in the phage-treated and control series.

	TREATED WITH CHOLERAPHAGE			NOT TREATED WITH CHOLERAPHAGE		
	Cases	Deaths	Percentage, mortality	Cases	Deaths	Percentage, mortality
Total number of cases in which no vibrios were isolated.	30	4	13.3	38	6	15.8
* Total number of cases not examined.	19	15	78.9	16	10	62.5

* These include all cases that were admitted and died before it was possible to collect any samples from them.

In the group of cases in which no vibrios were isolated our therapeutic bacteriophage seems to have had an unfavourable result. Clinically some 80 per cent of these cases were undoubtedly cases of cholera and this result is not understood. Further investigation of such cases is necessary before any conclusions can be drawn.

From a consideration of the results reported above it is evident that bacteriophage does not produce any dramatic effects. In our experiment to evaluate the use of bacteriophage on alternate cases of cholera we have not met with the striking results obtained by some of the previous workers. We have, however, definite evidence that bacteriophage is of value; particularly that cholera-phage, as prepared by us, acts effectively in the case of patients passing agglutinable vibrios. We have used just one criterion, the criterion of recovery or death, irrespective of the age, severity, the delay in treatment and other factors which undoubtedly

phage series than in the control series. Cases receiving phage are discharged sooner from hospital, they secrete vibrios for a smaller number of days and in general run a clinically milder course. There is less tendency to the development of pneumonia but these and other clinical conditions are not suitable for statistical analysis. The general impression of experienced workers in clinical charge of cases is that uræmia and other deadly complications are often averted, or, if they supervene, are milder in the phage-treated series. The development of uræmia is such a marked clinical feature that definite records are available. We have carefully analysed the clinical records of all cases and find that the number of patients developing uræmia in the phage-treated series is approximately half the number developing uræmia in the non-phage series. Table VII and the graph show the incidence of uræmia in cases grouped together according to the bacteriological findings.

TABLE VII

Showing the incidence of uræmia in the phage-treated and non-phage control series. The cases have been arranged in different groups according to results of the bacteriological findings

Group		TREATED WITH CHOLERAPHAGE		NOT TREATED WITH CHOLERAPHAGE	
		Number of cases	Incidence of uræmia, per cent	Number of cases	Incidence of uræmia, per cent
1	Cases in which agglutinable vibrios only were isolated.	219	12	244	33
2	Cases in which agglutinable and inagglutinable vibrios were isolated.	118	23	125	31
3	Cases in which inagglutinable vibrios only were isolated.	61	5	74	14
4	Cases in which vibrios were not isolated ..	234	5	194	10
5	Cases in whole series excluding the cases not examined.	632	11	637	23

play an important rôle in determining the issue. We have submitted cholera-phage to a very severe test and have maintained strict and adequate controls in our experiment. The results, which are based on a number of cases sufficiently large to justify the drawing of conclusions, do in our opinion indicate that the bacteriophage used by us was of definite value as a therapeutic agent, and that the reduction in the death rate is as great as one could reasonably expect in a disease that naturally runs so rapid a course and has such a high death rate.

We have analysed various other clinical data. We find that there is an appreciable difference in the phage-treated and control series of cases. The patients are less toxic, there is less dehydration and fewer 'salines' are required in the

Conclusions

1. A series of 1,369 cases of cholera admitted into the cholera wards of the Campbell Hospital during the year ending 30th July, 1935, have been investigated. Of these, 684 cases were treated with specially-prepared cholera-phage and 685 were not treated with cholera-phage. This selection in the two series was made by taking alternate admissions into the wards.

2. Comparison of the results of the experiment, taking recovery or death as the sole criterion of the value of cholera-phage, shows that bacteriophage has caused a real reduction in cholera mortality in cases passing vibrios and that this reduction is more marked in those cases passing agglutinable vibrios.

GRAPH

Figures of table VII shown in graphic form.

3. There is no significant effect on cases passing inagglutinable vibrios only or in cases bacteriologically negative.

4. There is marked reduction in the incidence of uræmia in the phage-treated series.

Acknowledgments.—We are grateful to the Indian Research Fund Association for a grant which enabled us to undertake this work. We would also acknowledge the help given us by Lieut.-Col. N. C. Kapoor, I.M.S., late Superintendent of the Campbell Hospital, Dr. S. N. Choudhuri, the Resident Medical Officer, and the staff of the cholera ward. A great deal of help was asked from each member of the staff of the cholera ward of the Campbell Hospital and was most willingly and ungrudgingly given us. We are also grateful to Dr. Raja for submitting our figures to statistical analysis. Finally, we would record our great sense of loss and of sorrow at the death of Dr. A. N. Sen, teacher of infectious diseases, who for many years has given us most valuable help and whose long experience in cholera work was invaluable to us.

AGAINST ORTHODOXIES IN RABIES

By S. D. S. GREVAL, B.Sc. (Punjab), M.D., Ch.B.,
D.P.H. (Liverpool)

MAJOR, I.M.S.

*Officiating Imperial Serologist, Government of India,
Calcutta School of Tropical Medicine*

(THE material for this communication was collected in 1932 when the writer was officiating as Director at the Pasteur Institute of India, Kasauli*).

Infectivity of the biting animal versus susceptibility of the victim

Mortality in untreated cases bitten by rabid animals is low. The following statements taken from the literature are typical:—

'Infections from rabid dogs were said to occur in 16 per cent of bitten individuals, whereas 80 per cent of cases bitten by rabid wolves are said to become infected. Inasmuch as the lesions caused by wolves are more extensive this increased infectivity may depend on the amount of virus introduced' (Horder and Mathews, 1929).

'Not all persons bitten by a rabid animal develop the disease, the site and number of bites influencing its development. About 40 per cent of dogs and 16 per cent of human beings who are exposed become infected' (Williams, 1930).

'The following estimates of mortality among the bitten and untreated have been made on various cases by different workers: Doebert—14.8, Hogyes—15, Marx—6 to 8, and Babes about 5 per cent. Figures collected at Kasauli from cases of persons who have come for treatment, but have received little benefit from it on account of late arrival, show that the percentage mortalities amongst untreated persons who have been bitten on the face, arm and leg must be greater than 9.5, 1.6 and 0.9 respectively. In dealing with such mortality figures it is well to remember that they have been calculated from large numbers of collected cases, involving large numbers of biting animals. They refer to the probability of death from the bite of an animal of average infectiveness. The infectivity of the biting animal is known to vary widely both amongst individuals and according to the stage of the disease. Thus in some cases it would appear that the biting animals are highly infective, and give rise to a mortality of 80 or 90 per cent amongst the creatures which they have bitten, whereas in others they appear to be incapable of transmitting infection at all' (Harvey and McKendrick, 1923).

With the exception of the last part of the last statement the impression created by these statements is that man is not a very susceptible subject to rabies from a rabid dog. The object of this communication is to point out that there is no justification for such an impression. At least equally possible is the assumption that the

infectivity of the rabid dog varies. Immense strength is added to the assumption by the well-known fact in experimental work that some street viruses (1st passage) are almost inert, while others are almost cent per cent lethal.

On the hypothesis of variation in infectivity the enormous difference between the average mortality of 16 per cent and the extreme mortality of '80 or 90' per cent can also be explained in terms of simple arithmetic. There must be many more viruses of 0—16 per cent mortality (= infectivity) than of 16—'80 or 90' per cent mortality (= infectivity) to give an average of 16 per cent mortality (= infectivity). In fact the majority of viruses must be non-infective, for chances of the viruses being non-infective are greater than of the human beings being so capriciously distributed with regard to susceptibility, that, though sometimes an '80 or 90' per cent infection results, on an average it is only 16 per cent. The presumption is strongly in favour of a variation in infectivity as opposed to a difference in susceptibility.

Incidentally, the fact that bites from wolves give a higher mortality figure would suggest better, more natural and original conditions for the 'maturation' of the virus in forests than in inhabited areas, if the factor of the greater severity of the bite could be controlled. The writer (Greval, 1932 and 1933) has contributed to this view in connection with rabies in the wild carnivores.

The supposed greater susceptibility of the dog may be entirely due to the fact that dogs bite dogs mostly on head and neck, parts which anatomically are better suited for the planting of the infection.

The question of susceptibility versus infectivity would hardly have arisen if it were not so difficult to obtain correct health returns of untreated and bitten cases fulfilling these two conditions: (i) The cases should fall into batches bitten by the same animal on the same day and (ii) there should be at least one death from hydrophobia in each batch. It is only by analysing batches of this kind (controlling factors of mechanical and anatomical importance) that a true susceptibility of man to hydrophobia could be worked out. As an illustration is given the following batch recorded at Kasauli:—

Locality of the incident—Jaipur (State).

Date—14th August, 1932.

Number of persons bitten—4.

Number of deaths among the untreated cases up to 15th October, 1932—3.

These are the details: Four men were bitten by the same dog on the same day; the dog was then killed; about 55 days later two of the men developed hydrophobia and died; the other two, then, started for Kasauli; arriving at Kasauli one of them, a class III case (Hempt), developed hydrophobia (after one day's treatment = no treatment) and died.

*[Note.—The publication of this paper was withheld in 1932 in deference to the opinion of the Director of the Pasteur Institute, Kasauli, who looked upon it as a criticism of the treatment given in the Institute. In the annual report of the aforesaid Institute for the year 1933-34, however, a list of serious post-treatment sequelæ has appeared (part II, p. 4). It is presumed, therefore, that the objection no longer holds.

The paper was written under two names. The name of the second writer, who did not wish to have the paper published under his name, has been omitted. Otherwise the paper is materially unaltered.]

Assuming that the fourth case, a class II case (Hempt), would not have developed the disease even without the treatment (an assumption not really justified in view of the different degrees of bites having different incubation periods) the mortality from the bite of this dog in untreated cases was 75 per cent.

Deaths from licks

'Opinion is equally divided as to the necessity of submitting to anti-rabic treatment persons whose skin has come into contact with the saliva of a rabid animal (or human being suffering from hydrophobia), if there be no visible break in the continuity of the skin surface'.

Resolution II, 4, of the International Rabies Conference, League of Nations (1927).

The common practice in India is not to advise treatment for licks if there are no apparent skin lesions. The following military case is quoted :

Lieutenant A., aged 26.

Previous history: His dog died of rabies some six weeks ago. States that on the occasion the dog caught hold of his forearm in its mouth but there was no abrasion on the skin. No anti-rabic treatment given.

History of malaria, August 1931: First felt unwell 20th August, 1932, when he experienced pain and hyperæsthesia of his right forearm and also felt tired. Bitten four times by wasps few days ago. On 21st August, 1932, he was still off colour and had a slight rise of temperature. He read up the symptoms of rabies and reported sick on 22nd August, 1932.

Present condition: Complains of being tired and of very slight discomfort in his right forearm. Is very anxious and when being examined collapsed and vomited. On being given a glass of water he found difficulty in swallowing, and gasped for breath. Heart shows a mitral murmur when patient is sleeping (lying?). Sound normal when erect. Temperature, 99.6°F. Respiration, 18. Pulse, 72. No headache or other symptoms. History and condition give rise to the suspicion of hydrophobia.

Later: Patient seems more comfortable. Vomited. [Bromide and chloral given.]

23rd August, 1932. Patient did not sleep well. Vomited his sedative. He is still very anxious, but has some control over his dysphagia. [Bromide and opium given per rectum.]

5 p.m. Patient is much better and has slept. His improvement may be due to the effect of his sedative not having worn off: or it may be genuine improvement.

7-30 p.m. Patient is not so well. His irritability is increased.

9 p.m. Patient is worse and appears to be definitely suffering from rabies. His saliva is rejected, his buccal muscles are working and his irritability is so intense that he is with difficulty kept in bed. Place on 'dangerously-ill' list to-morrow [morphine, grain ½, given].

11 p.m. Patient is worse. He looks exhausted and there is now some spasm of the legs; morphine repeated. 24th August, 1932. After a restless night, patient collapsed suddenly and died at 8-20 a.m.

Copy of a letter dated 24th August, 1932, from Major L. M. N., Staff Surgeon,.....Lines, X, to the Officer Commanding,.....X.

On Sunday, 26th June, 1932 (forenoon), I was sent for by Lieutenant A., who informed me that his dog had gone 'mad' and had bitten about seven other dogs before it could be secured. He had it sent to the Cantonment Veterinary Officer for observation immediately and I was informed that it died later that Sunday. I carefully examined Lieutenant A's arms, forearms, hands and knees and legs and could find no signs of any recent abrasions or cuts and asked him if

at any previous time within the last week or so he had been bitten or had any cuts or scratches that might have been licked, but he could not recollect any. He admitted that he had often been licked whilst playing with the dog and said that the only possible way he might have got any dog's saliva in contact with abrasions of his skin was possibly when he rubbed his cheeks or chin with his hands after shaving. There were no signs of cuts or abrasions on his face when I examined him. I put it to him that he could have a course of anti-rabic treatment if he wished to but that as he had no signs of any cuts or abrasions that I would not order him to have it.

This is a very unfortunate case. From the careful examination carried out by the Staff Surgeon there would appear to have been no urgent indication for anti-rabic treatment when the patient was seen immediately after the dog became rabid.

(Sd.) O. P. Q. R.,

Major, R. A. M. C.,

D. A. D. P. X. District.

3rd September, 1932.

An unfortunate example of the risk taken by patients who decline anti-rabic treatment, even when there appears to be no possibility of infection.

(Sd.)

Lieut.-Col., I. M. S.,

3rd September, 1932.

This is clearly a case of death from a lick with no visible break in the continuity of the skin surface.

The following case was recorded by Malone (1928) in the Annual Report of the Pasteur Institute of India, Kasauli, for 1928 :

'Case 16; table XIII; European; dog proved rabid; saliva came in contact with scratches on both hands; patient was not bitten by the dog.

This is the first death from hydrophobia in a patient "licked" by a rabid animal and treated with carbolized vaccine'.

The table XIII shows that the patient, a female, class I (Hempt), started treatment on 7th May, 1928, and finished on 10th May, 1928. Death occurred 90 days after the lick. The treatment, to say the least, was half-hearted. In this case scratches are admitted. They were not, evidently, regarded as serious.

The Annual Report for 1908 gives another case of infection from a small scratch, recorded by Carter (1908) :

'Two boys aged about 12 years were returning from school when one was unexpectedly attacked and bitten by a rabid dog which escaped into the jungle. The boys state that the dog was furious and frothing from the mouth. The companion of the boy bitten, not observing a small scratch he himself had on his left thumb, touched the wound of his friend. The boy bitten came to Kasauli for treatment, whilst his companion, who received no treatment, developed hydrophobia and died 40 days after the accident'.

Here again a 'small' scratch was disregarded even though the dog was definitely recognized as rabid.

It is admitted that these occurrences are rare. The fact, however, remains that they do exist. Possibly some of the cases of unexpected death from unexplained asphyxia or tetanus are really cases of hydrophobia in which the infection has not been acquired in the usual way by a bite.

In the opinion of the writer, all cases of licks (class I, Hempt) should be given at least the same treatment as cases of superficial bites (class II, Hempt). He has taken three anti-rabic courses of varying strength, during the last 12 years, after accidental contacts with known infectious materials, in the laboratory.

Sequelæ of anti-rabic treatment

A. Paralysis of anti-rabic treatment.

'We have come to the conclusion', says Remlinger (1927), 'that certain institutes conceal their cases'. Or, again, more charitably (Remlinger, 1927a), 'certain mild cases of facial paralysis or retention of urine passed almost unnoticed. Other cases occur after the conclusion of the treatment, when the patient has already returned home. The director of the anti-rabies institute is either not notified at all or is simply informed by letter. Such a communication attracts little attention. Soon the matter is forgotten, and it is with quite good faith that a negative reply is given to a demand for information'. The following cases have been collected at Kasauli or centres supplied from Kasauli, between March and October 1932. The severity of lesions has varied. No death has occurred. Presumably the recovery has been complete:

1. *Incontinence of urine in a European child, aged 2½ years.*

'In May 1931 my daughter then being 2½ years of age had a course of anti-rabic treatment.

I should like to know if as a result of the treatment she could develop bladder trouble, as since that date she has been a hopeless bed-wetter.

The desire to urinate comes on her quicker than we can get her to the commode. The doctor advised us to give her no liquids after 4 p.m. and awaken her frequently during the night. We have tried this but with little success. I would be very grateful for advice in this matter and to know if she will grow out of this rather unpleasant habit'.

P.S.—The trouble has grown on her very gradually.

A 5 per cent brain substance vaccine had been used. Attempts at obtaining more information through medical men did not succeed. But on 15th October, 1932, the father wrote:—

'My little girl is progressing very favourably and is very gradually growing out of the habit of wetting her bed. If I may be allowed to express an opinion, I think it is really bladder weakness and not any after-effects of the anti-rabic treatment she had. Thanking you.....'

If this case is a case of paralysis of anti-rabic treatment, two points are worth recording: (1) age incidence, children having been considered practically immune from the paralysis and (2) incontinence instead of retention.

2. *Pain in hands and difficulty in micturition in an Indian patient.*

'With reference to my case no. 4248, dated 1932, of p. 4, I beg to inform you that from the time I came to Benares I feel very much heat, on account of this reason my mind is roaming always, besides this I have got pain in my both hands and feel some trouble in making water. Nowadays I am in Benares. Please reply me soon as I am in great trouble.

For this act of kindness I shall remain thankful to you'.

A 5 per cent brain substance vaccine had been given. No further information could be obtained through a medical man. Presumably the patient was suffering from a mild neuritis of the arms and a paresis of the bladder. Incidence in an Indian case is noted.

3. *Paralysis of the bladder and the rectum with a paresis of the legs in a European patient.*

'With reference to your letter no. SP/12848, dated 7th August, I would advise that towards the completion of the anti-rabic treatment in L. my stomach became very tender and after the treatment was finished the inflammation appeared to settle in both my groins, showing as a red weal from the fork to the buttocks. I went to D. for four days' rest but I felt decidedly off colour, developing severe headache. I returned to A. and a couple of days later I developed fever and severe pain in my back, making it difficult to find a comfortable spot to sleep. After a couple of days with no relief, my bladder and bowels refused to function entirely, so I went into the M. hospital L., for treatment under Colonel N. and Colonel B. and remained there 5 or 6 days. The urine was taken off by means of a catheter for three days after which I began to pass urine slowly unaided, and thereafter steadily improved. The only medicine I was given in hospital as far as I know was P. C. Before and whilst I was in hospital also for about a month afterwards I had a peculiar feeling in my legs and feet as if they were semi-paralysed. This has now completely worn off.

I would mention that whilst taking the anti-rabic treatment in L. necessitating a motor ride of 70 miles each way, it was exceedingly hot, and probably the long motor drive in the heat had something to do with my subsequent illness.

The above particulars are as correct and complete as I can remember and I trust will be of use to you'.

Yours faithfully,
F. E. B.

This is definitely a case of paralysis of anti-rabic treatment with symptoms typical of the involvement of the cord in the lumbar region. The fact, however, does not appear to have been recognized by anybody at any of the stations mentioned (all big stations). At one of the stations (D.) the likelihood of an accidental puncture of the urinary bladder, during the course of injections, was seriously considered. This consideration and the consequent fear on the part of another patient who had gone to Kasauli from D. for an anti-rabic treatment was responsible for an enquiry into this case which otherwise would not have been recorded at all.

The red weal locally on the point of injections or elsewhere at a distance is known to occur.

A 2 per cent brain substance vaccine had been given for licks (class I, Hempt).

4. *Paralysis of the bulbar type in an Anglo-Indian girl, aged 8 years.*

'..... On the 10th August my youngest daughter was bitten on her feet by my own bull-terrier pup, aged three months. This pup was definitely rabid..... developed paralysis of the legs and died on the 14th night. My child had her bites, amounting to nearly 16 in all, cleaned with ether.....and within half an hour to one hour had her anti-rabic injection, classes III and IV vaccine. Nothing untoward happened till the morning of the 23rd August when all she complained of was that she was very weak and had to be carried to the bungalow, a distance of twenty yards from the B. M. Hospital. That evening we noticed her voice

had sunk to a whisper. She was suffocated and could not drink or eat anything. She was taken into B. M. Families Hospital at M. For four days her condition was critical. Her eyes were blood-shot and at the very attempt at swallowing fluids only came up. Three days later she got a certain amount of paralysis of her left arm. Immediately on completion of treatment she broke out all over with the huge sores and is now recovering slowly.

Remarks on the treatment card by the anti-rabic centre at M.

Child completed treatment on 23rd August, 1932, and admitted into hospital on 25th August, 1932, suffering from laryngitis, acute catarrhal, with some aphonia, no pyrexia and no other unusual symptom. Throat swab negative to K. L. B. Some congestion of throat. No membrane. Treated with inhalation and throat paint. Discharged 30th August, 1932, normal.

The two statements taken together exclude diphtheritic paralysis otherwise there is not much agreement between them. The father of the patient, let it be noted, is also a medical man of some experience. There is no reason why this case should not be diagnosed as one of bulbar lesion. Such cases have been described as representing a culmination of the Landry's ascending type of paralysis of anti-rabic treatment. 'There is difficulty in closing the mouth and the eyes, and in making any sound (the patient speaks only in a whisper and without being able to articulate distinctly). There is difficulty, too, in swallowing, fluids being returned through the nose or causing coughing by entering the larynx, and syncope, tachycardia and dyspnoea supervene. After an extremely anxious time, during which it was doubtful whether or not the bulbar symptoms will cause death at any moment—and this indeed occurs in 30 per cent of the cases—the symptoms begin to improve and then disappear in an inverse order to that in which they developed..... The recovery is complete in a few days or at most in two or three weeks. Weakness, however, may persist for a very considerable time, with a tendency to fatigue, especially in the lower limbs' (Remlinger, 1927b).

Accepting this case as one of paralysis of anti-rabic treatment, then, there are three points to note: (1) age incidence (children not being regarded as liable), (2) race (only Europeans in India are regarded as liable) and (3) primary bulbar involvement (as opposed to a culmination of the Landry's ascending type of paralysis of anti-rabic treatment).

The significance of the 'huge sores' is not understood.

A 5 per cent brain substance vaccine had been given for deep and multiple bites (class IV, Hempt).

B. Epileptiform seizures during anti-rabic treatment.

Only two cases are recorded. One occurred at Kasauli and the other at one of the anti-rabic centres served by Kasauli. Both of them caused quite a commotion at the time but recovered.

Case 1. A military case, European, treated at a military centre.

27th July, 1932. Saw patient at 11-30 p.m. Tonic contraction. Asphyxia. Cyanosis present. Has been having anti-rabic treatment. Some paralysis of epiglottis and great hardness of abdominal muscles. Artificial respiration had to be resorted to on three distinct occasions following contractions. Pulse thready. Sweating profusely. No foaming or frothing from mouth. Unconscious and unable to speak. Did not pass urine or faeces unconsciously during spasm.

Condition improved on applying mouth gag and drawing out tongue with tongue forceps.

The Orderly Medical Officer saw patient and left him in a quietened condition.

28th July, 1932. Quiet and restful. Pulse normal. Respiration normal.

The fits occurred after 10 injections. The treatment was discontinued.

Case 2. A non-military case. European treated at Kasauli.

C. G. R., male, aged 49. Under treatment for a class III bite. History of an operation on the brain and treatment with radium several years ago in London.

On the fifth day of treatment complained of loss of sensation in the legs below the knees. Pressure on Achilles' tendon without response. Knee, ankle and plantar reflexes absent. Loss of sensation to pin-pricks below the knees. Pupil normal. Throat and conjunctiva normal. Superficial abdominal reflexes normal.

The general feeling described as one preceding a 'brain attack' to which the patient apparently had been subject on occasions under mental strain. Treatment suspended.

The patient seen in his hotel next morning in status epilepticus. Several such attacks for two days with intervals of consciousness. Sedatives given.

Recovery complete in a week. Patient left fatigued and tired looking (not altogether due to the fit—domestic worries). In another week the patient left for his station in a normal condition, having taken a modified course of treatment.

No details could be obtained about the previous operation of case 2. The case cannot be definitely regarded as representing a sequel of the anti-rabic treatment. But for case 1 it would not have been described. It shows, however, that even under stormy conditions in the brain a modified course of treatment (1 per cent brain matter) is possible.

Both these cases were being treated with 5 per cent brain substance vaccine when the fits occurred.

C. High temperature resulting from anti-rabic treatment.

A slight rise of temperature during anti-rabic treatment is known to occur. It may even simulate the chill and the sweat of malaria. After excluding malaria by a blood examination no further notice need be taken of it. An interruption of treatment is generally not called for. In 1932 there occurred at Kasauli, however, the following two cases of high temperature necessitating an interruption of treatment:

Case no. 3454 (Kasauli), M. H., European, adult, female. Under treatment for class III bite. History of malaria. Blood repeatedly negative. Admitted 27th May, 1932. Did not complete treatment.

Case no. 3772 (Kasauli), B. T. S., Indian, 28, male. Under treatment for class III bite (Hempt). No history of malaria. Blood repeatedly negative. Admitted 12th June, 1932. Discharged 28th June, 1932.

After the first three or four injections the temperature would shoot up to 103-104°F. a few hours after an injection and would remain stationary until midnight when profuse sweating would occur. Next morning the patients would feel exhausted and refuse treatment. If given a day off they would look and feel quite well, and partake (within prescribed limits) of the social amenities of a pleasant hill station in summer. There was a definite loss of weight. The first case gave up the treatment. The second case was given several days off. Both the cases were being injected with a 5 per cent brain substance vaccine.

D. Troublesome insomnia resulting from anti-rabic treatment.

Two cases occurred that caused considerable anxiety at the time. They recovered, presumably, completely.

Case no. 3454 (first case under C) on her return home developed a very troublesome insomnia. She wrote:—

12th August, 1932.

My husband suggests that I should write and ask you if you could advise me about the after-effects of the dog treatment. Ten days after the last injections I had fever on and off which was proved definitely not to be malaria and then I gradually became unable to sleep at night, until now even sleeping draughts won't help me, and for the last two or three nights I have not been able to sleep until daylight. It's really awful, and we wondered if any other patient had suffered like this, and if you could help me in any way'.

Advice was given. On 24th October, 1932, information was received from her local medical adviser that she had left the station and that the insomnia had improved.

Case no. 5627 (Kasauli), F. L., European, aged 40, female. Treated for class III bite (Hempt). Admitted 15th September, 1932. Discharged 29th September, 1932. Developed insomnia a week after completion of treatment.

Her husband, who had come for anti-rabic treatment later than his wife and had brought her back to Kasauli with him, stated that she had not slept at all the previous night. She looked tired and was inclined to be tearful. Full doses of bromides, an atmosphere of quietness and encouraging remarks on the capacity of the nervous system to stand the strain like that of insomnia restored her to the normal in four days.

A feature common to both the cases was a previous abdominal operation involving probably the pelvic organs. A 5 per cent brain substance vaccine was used.

E. Other complications of a more-or-less local character.

One case of dry and scaly condition of the skin persisting long after the treatment, reported from one of the centres supplied from Kasauli, was the only one that could be included under this heading.

(i) Erythematous patches at the site of inoculation, (ii) scarlatiniform erythema, (iii) urticaria, (iv) acute abscess and septicæmias to which they may give rise, and (v) sub-acute abscess in corpulent subjects, referred to by Remlinger. (1927c), were not seen.

Comments on the sequelæ

Out of the four cases of paralysis three occurred with intensive treatment. The fourth case which, however, was the only typical case of paralysis of anti-rabic treatment occurred with a mild treatment. Opinion generally held is that the incidence of paralysis is independent of the intensity of treatment. It may be so.

Out of the six cases of other complications, fits, high temperature and insomnia, all six occurred with intensive treatment.

The racial influence may be proportional to the facilities for expression.

Carbolization of the vaccine does not ward off the sequelæ. It would not be necessary at all to state this point if the opposite were not so widely believed in India by the general medical profession. In the early history of the Pasteur Institute of India, Kasauli, with introduction of a carbolized vaccine, cases of paralysis of anti-rabic treatment appear to have been absent. Cunningham in 1930 (Cunningham, 1930), however, reported four cases. Later two cases were reported by Shortt (1931) in the Annual Report for 1930. The writer is inclined to believe that the apparent lack of the sequelæ was due to a lack of an efficient system of correspondence. Such a system was evolved and perfected by Cunningham.

In spite of the fact that the morbid anatomy of paralysis of anti-rabic treatment (and presumably of all allied complications explicable on the basis of a dysfunction of the nervous control) has assumed a formidable aspect, in changing from a vascular lesion (Remlinger, 1927d) to a demyelination (Bassac and Grinker, quoted by Hadfield and Garrod, 1932), such as occurs in post-vaccinal encephalitis on the one hand and in disseminated sclerosis on the other, there is some satisfaction in knowing that all the cases reported have completely (with a proviso of probability in two only) recovered.

No attempt has been made to calculate percentages of the various sequelæ as it is felt that all cases of sequelæ have not been collected. The first case of paralysis described occurred amongst cases treated in 1931. All others occurred amongst cases treated in 1932. The total number of cases treated at Kasauli and centres supplied from Kasauli in 1931 was 11,147. Figures for 1932 are not yet available. [The number treated in 1932 was 12,801.—Editor, I. M. G.]

Summary

1. The importance of the infectivity of the rabid dog, as opposed to susceptibility of the victim, in the development of hydrophobia is discussed.

2. Deaths from licks of rabid dogs have been reported from records of the Pasteur Institute of India, Kasauli. Special attention has been

and

A. VASUDEVAN, M.B., B.S.

(From the Department of Pathology, Medical College, Madras)

UNTIL recently, tumours arising from the epithelium of the skin and its appendages were generally known as carcinoma of skin and no attempt was made to classify them into various types according to the predominant type of cell of the new growth. To Krompecher (Kaufmann, 1929) belongs the credit of separating the various forms of skin carcinoma into :—

1. A basal-celled type called 'basal-cell epithelioma'.

2. A squamous-celled type.

Some authors call them non-cornifying, and cornifying carcinoma or acanthoma. These two types differ not only in their histological characters but also in their clinical course, response to treatment and progress. Hanse-mann (Ewing, 1928) contends that since all

(Continued from previous page)

drawn to a recent death from licks with 'no visible break in the continuity of the skin surface'.

3. Sequelæ of anti-rabic treatment have been recorded. Deviation from the type has been noted in cases of paralysis. Cases of high temperature, insomnia and fits have been included.

epithelial tumours arise from the basal cells the term basal-cell carcinoma was not quite suitable. But Krompecher's choice of term may be justified on the ground that basal-cell epithelioma is composed of basal cells which retain their morphological characters throughout their existence, in contrast to the squamous-cell carcinoma in which the basal cells are further differentiated and lose their original characters. Epithelial tumours of the skin showing a tendency to reproduce the structure of dermal glands are designated as adenoid epithelioma. These tumours may show cystic spaces and are then known as epithelioma adenoides cysticum. We have come across three cases of this type which are reported here.

REPORTS OF CASES

CASE I. Clinical history.—Female, aged 30 years. The trouble began one year ago with headache and pain in the left eye. The latter gradually protruded and vision began to fail. The conjunctiva, congested and œdematous, bulged in front of the socket and the lids could not be closed over the eyeball. Gradually headache which was originally severe changed into pain of a dull character and vision became completely lost.

On admission, she showed marked exophthalmos, the eye projecting about one inch in front of the socket. The eyeball, which was collapsed and tensionless, was situated at the summit of the swelling. On palpation through the conjunctiva, a firm lump appeared to fill the socket entirely.

The conjunctiva was incised round the eyeball which was excised. There was no sign of infection within the eyeball. The growth felt hard and appeared to fit tightly in the socket. On passing the handle of the scalpel round the growth, it was possible to separate it from the surrounding bony walls without force, it was not attached to the periosteum except at one spot, even here not firmly. There was very little hæmorrhage. At the operation, the lachrymal gland was not identified, as such, and the surgeon thought that it had either entirely atrophied as a result of pressure of the tumour, or that the growth arose from the gland and had replaced it. There were no metastases. The patient left the hospital two weeks later in good condition and well satisfied except for the loss of the eye.

Naked-eye appearance of the growth.—The growth, $1\frac{1}{2}'' \times 1''$ in size, was conical in shape, and felt firm like a hard fibroma without any glandular lobulation. In section, it presented a uniform greyish-pink appearance without oozing of any fluid.

Microscopic examination.—Section of the orbital growth under low power shows numerous cell collections of varying sizes which are separated from one another by bands of dense fibrous tissue. These cell masses contain a number of spaces of different sizes which are either empty, or containing either an acidophilic or a basophilic substance (plate I, figure 1). There is no stratified epithelium on the surface. Under high power, the periphery of a cellular mass is seen to consist of elongated cells bearing a close morphological resemblance to the basal cells of the epidermis which are arranged in a palisade manner (plate I, figure 2). The central zone of some of the cell groups consists of cells in various stages of disintegration, for example, those in the centre are devoid of nuclei and the remnants are acidophilic in reaction. As we proceed towards the periphery, the degeneration becomes less marked so that the cells at the extreme periphery are normal in their staining properties. Some of the cystic spaces are filled with a colloid-like substance. In others, a brownish amorphous substance is present. The contents are homogeneous, granular, or laminated. The cells internal

Fig. 1.—Note the cystic spaces of varying size filled with granular or amorphous material.

Fig. 2.—Showing wall of one of the cystic spaces under high power. The cells at the extreme periphery are elongated and are arranged in a palisade manner. The cells internal to this layer are in various stages of disintegration.

Fig. 3.—There is a large mass of cells in which are seen small cystic spaces. At one side are the hair follicles.

Fig. 4.—Note the atrophy of the surface epithelium and the subjacent cystic spaces. One of these, at the upper part is very large and contains granular material.

to the peripheral basal-cell layer are more or less round or oval shaped. The cytoplasm is small in amount and the nuclei which are round or oval are deeply stained. Mitotic figures are not noticed. There is no transformation of these proliferating cells into the squamous cells. The connective tissue stroma is infiltrated with plasma cells and lymphocytes and in some places shows a marked degree of hyaline degeneration.

CASE II. Clinical history.—None available. The patient, a female, had a small nodular growth on the eyelid.

Microscopic examination.—A section of the growth under low power shows skin epithelium which appears atrophic and lacking in the normal papillae, but the basal-cell layer is intact. Beneath the epithelium are seen cell masses containing clear spaces. Beyond the cell masses, at one side, there are smaller collections of cells with a central lumen. These are hair follicles and are embedded in a delicate connective tissue stroma (plate I, figure 3). A striking feature of the section is the close proximity of the cell groups to the surface epithelium without its actual invasion. Under the high power, most of the cystic spaces appear empty, but in a few of these commencing myxomatous degeneration may be seen with typical stellate cells. The impression gained is that the connective tissue stroma has been enclosed by the growing masses of cells with its subsequent degeneration from lack of nourishment. At the periphery, the cells appear more elongated than those at the centre. The cells are mostly long, spindle-shaped with fibrils. There is a marked degree of infiltration of the stroma with lymphocytes.

CASE III. Clinical history.—A female, aged 50 years, was admitted to the Government Hospital, Royapettah, Madras, for the treatment of a hard nodular swelling, the size of a hazel-nut, situated on the upper lip. The growth was painful, showed lobulation, and was fixed to the upper lip on the left side. None of the lymph nodes showed enlargement; duration two years.

Microscopic examination.—The section taken from the growth shows the epidermis to be thinned out; the papillae are atrophied over the tumour (plate I, figure 4). The cell groups are very close to the surface epithelium and are almost in contact with the latter. The cystic spaces are occupied by a basophilic substance probably mucoid in character. The spaces present a reticulated appearance which probably depends upon the degeneration of the cytoplasm and nuclei so that only the faint outlines of the cells remain. A few of the spaces show brownish granular material. The cells lining the cystic spaces are flattened and elongated. Hyaline degeneration of the stroma is seen in a few places. No lymphocytes, or plasma cells are seen in the connective tissue stroma.

DISCUSSION

Histogenesis.—Naturally, the most interesting question concerns the origin of these tumours. Krompecher derives them from the basal cells of the skin, hair follicles, sweat and sebaceous glands. This view has been accepted by the majority of workers but a few oppose it. Borrmann (Ewing, 1928) traces their origin to the basal epithelium; but, according to this worker, it is not the surface epithelium which gives rise to these tumours, but the embryonal cell groups which are derived from the skin and its appendages, and are situated in the corium; hence the name 'corium carcinoma'. It may be mentioned in support of this view that in the case of many early tumours the cell groups are isolated showing no connection with the epidermis and that they occur chiefly along embryonal fissures, chiefly of the face and in the salivary glands. Moreover, the partly

embryonal characters of the cells composing the tumours also favour this view. In some instances however one can see the stalk-like band of cells connecting the basal layer of the surface epithelium with the tumour cells underneath. But as the tumours grow, the connecting band for some reason is lost. This explains the apparently complete isolation of the tumour cell collections from the epidermis. It has already been stated that basal-cell tumours may arise from the hair follicles. They may show adenoid cystic characters, but differ from the others in producing long, fine and coarse fibrils. Mallory (1914) lays special stress on its origin from the cells of the hair matrix which form the hair and its sheath and whose capacity for differentiation is extremely limited compared to those of the epidermis. The cells develop large numbers of delicate fibrils and the tumours springing from these cells are composed of spindle-shaped cells with long, fine and coarse fibrils running in the direction of their long axes. This feature was very pronounced in sections of our case II and we are inclined to trace its origin to the cells of the hair shaft. It will be seen that basal-cell tumours may arise from the basal cells of the epidermis, hair follicles, sebaceous glands, and sweat glands or from misplaced embryonal basal cells in the corium.

The question of the exact source of the growth in case I is somewhat difficult. It was noticed at the operation that the lacrimal gland could not be identified by the surgeon and he concluded that it had either undergone atrophy from pressure of the growth or that the growth had originated from the gland itself. Assuming its derivation from the lacrimal gland, the possibility of its being of the nature of a mixed tumour has to be considered. Before proceeding further, it is necessary to discuss the nature of the mixed tumours. These tumours are composed of epithelial elements which may occur as alveoli, diffuse masses, or cell strands and mesoblastic tissue chiefly cartilage, mucous tissue and cellular connective tissue. The origin of these tumours has long been a subject for discussion and the present position may be summarized in the following statements:—

1. The theory of endothelial origin of the so-called mixed tumours has been abandoned since it was first shown by Hinsberg and later by others that the parenchyma in some specimens consisted of unmistakable glandular or squamous epithelium. The histological characters of the cells of these tumours are different from those of the endothelial cells of blood vessels. This tumour (case I) was originally reported as endothelioma from this laboratory, but on studying the section after many years, we, who had not seen it before, came to a different conclusion. It struck us that the contents of the cystic spaces were of unusual nature for an endothelioma. In a capillary endothelioma, the lumen of the vessels is either

empty or only shows a slightly acidophilic homogeneous material. In the case of hæm-endothelioma, of course, one finds blood corpuscles. The contents of the cavities in the case under discussion were of a varied character. Some were strongly acidophilic, others of different shades of blue. In either case the material was either homogeneous or granular. We were convinced from a study of the section that the material contained in the cystic spaces really represented degenerated cells, but it is possible that in some cases it was of the nature of a secretion from the glandular cells.

2. The epithelial origin of these tumours is now generally accepted, but the presence of cartilage in these tumours has been interpreted in various ways :—

(a) That the cartilage is derived from an embryonal cartilage in the neighbourhood of the gland or that both the cartilaginous and the epithelial elements spring from the multipotential cells.

(b) That the cartilage may be derived from the epithelium by a process of metaplasia (Krompecher). The transition of the glandular epithelium to the cartilage has been noticed by some observers and Ewing is convinced of the derivation of mucous tissue and cartilage from gland epithelium. Transformation of one type of tissue into another of the same class is well known, but such transformation does not take place between tissues of totally different types, for example, an epithelial tissue does not become changed into connective tissue, or *vice versa*.

(c) That the cartilage may be derived from the mucoid connective tissue by a process of metaplasia.

(d) That the so-called islands of cartilage consist merely of connective tissue stroma undergoing mucoid change in which the epithelial cells lie free in small spaces around which there may be a fibrillar condensation with a resulting pseudo-capsular arrangement around the cells (Fry, 1927). It may also be noted that the boundaries between the mucoid tissue and cartilage are not well defined, so that one merges imperceptibly into the other, giving the impression that the mucoid tissues are becoming changed into cartilage. In view of this interpretation of the mesoblastic elements, the so-called mixed tumours are to be regarded as benign epithelial growths with mucoid degeneration which results in the formation of some material which looks like cartilage.

From a study of the literature and of the material in our collection, it appears there are two sources of the mixed tumours :—

(i) Some of these originate from the ducts and acini of the glands and present an adenomatous structure. As these spring from differentiated cells the tendency to form alveoli and glandular structures is distinctly noticeable and well marked. They form part of the gland and many of them are not encapsulated.

(ii) Others arise from embryonal cells, misplaced or located in the gland itself. Branchial remnants may also serve as the origin of such tumours. Originating as they do from comparatively primitive cells, the tumour cells do not form definite glandular structures but only show a superficial resemblance to these. They show the structure of the basal-cell or adenoid cystic epithelioma, and are usually encapsulated and are extra-glandular. Our case I belongs to this category.

Structure.—While the initial response in this group of tumours is a proliferation of the basal cells, the ultimate results vary greatly and thus they come to present different clinical and histological characters. For example, cystic spaces may be found in the cell masses, which may be formed in various ways :—Firstly, the tumour cells during the process of their growth may enclose an island of connective tissue which is thus cut off from its blood supply and undergoes degeneration. This is clearly seen in sections from our case II. Secondly, the wall of the blood vessel which is surrounded by tumour cells may degenerate giving rise to a cystic space, limited by tumour cells. Thirdly, which is probably the commonest, the cells situated in the centre of the solid cell groups themselves may degenerate from lack of nourishment. We have noticed in one and the same slide all stages of development from a commencing degeneration of the central zone of the cell masses to fully formed cystic spaces containing cellular debris, mucoid or colloid material. Sometimes the walls of the cysts have been known to disappear and the colloid undergoes calcification. But this has not been noticed in the present section. Some authors have reported the transformation of the proliferating basal cells into squamous cells. We have not noticed this change in any of our sections, but considering the capacity of the basal cells for differentiation into squamous cells, such an occurrence is not at all unlikely.

Classification.—Krompecher divides the basal-celled tumours into six types according to certain forms of growth and of degeneration. This classification appears to be somewhat complicated. Frieboes (McCarthy, 1931) proposes a simple one, which considered from the clinical standpoint and histological changes is convenient and useful. This may be slightly modified for purposes of description as follows :—

Type I. *Carcinoma basocellulare solidum* of Krompecher, which is composed of solid masses of cells. This embraces all the tumours commonly known as the basal-celled tumours proper and is called reticulated epithelioma by Ewing.

Type II. *Adenoid epithelioma*.

(a) Without cystic spaces. Simple adenoid epithelioma is composed of cells arranged in the form of alveoli lined or filled with cylindrical or cuboidal epithelial cells. There are no cysts.

PETIT MAL OR PYKNOLEPSY

By J. NORMAN PACHECO, M.R.C.S. (Eng.),
L.R.C.P. (Lond.), I.M.D.

Officiating Superintendent, Indian Mental Hospital,
Kanke (Ranchi)

EPILEPSY is an age-old yet ever new and common morbid clinical state, and is one of the great problems that still baffles medical science.

(Continued from previous page)

These tumours originate either from the dermal glands or hair follicles or from the embryonal basal cells which differentiate into glandular structures.

(b) With cystic spaces—cystic adenoid epithelioma, Brooke, 1892. It appears to us that some closely related conditions have been described under different names such as trichoepithelioma, adenoma sebaceum and syringoma on insufficient grounds. The first two are so closely related to epithelioma adenoides cysticum as to be indistinguishable clinically and pathologically. Syringoma is said to differ from epithelioma adenoides cysticum in that it is not hereditary. Considerable confusion has been caused by the introduction of these terms and we are of opinion that they should be avoided as far as possible.

Type III. *Cylindroma*, or *nævus epithelioma cylindromatosis*, is histologically characterized by hyaline change in the connective tissue surrounding masses of tumour cells. Clinically it can be distinguished from other types of basal-cell tumours by a large and more variable size of the lesion which is not pedunculated and occurs usually in the scalp.

A type intermediate between I and II has been described, but the clinical and morphological characters do not appear to be so well defined as to describe it as a separate clinical or pathological entity.

Summary

Three cases of epithelioma adenoides cysticum are described with special reference to their histopathology. In the first case, the tumour has originated either from the lacrymal gland or from its neighbourhood and the grounds on which this has been regarded as a cystic adenoid type of the so-called mixed tumour have been stated. The derivation of case II has been traced to the basal cells of the hair matrix. The histogenesis, structure and classification of these tumours are considered in some detail.

Though Hughlings Jackson described it as a 'disease characterized by occasional sudden, excessive, rapid, local discharges of cortical grey matter', the more modern view is that epilepsy is not a disease but a symptom, a phenomenon of a state, the causes of which are many.

The approach to this complex problem is by no means lightened when one reads the terse summing up of the modern views on this subject by an eminent neurologist, Kinnier Wilson, who says, 'The truth is, the condition defeats us on many grounds; its ætiology is heterogeneous, its semeiology indeterminate, its pathology dubious, its pathogenesis conjectural, and its therapeutics empirical'. To diagnose a case as major epilepsy may be as easy as recognizing the signs of a fully-developed psychosis, but to trace it down to its ætiological basis is a different matter. The various conflicting ætiological theories—vascular, humoral, autotoxic, reflex, etc.—offer no pragmatic clue as to what part of the vast cortical field is stimulated, and how. Does the epileptic 'discharge' begin in one particular area and then spread to others, or is the whole cortex stimulated at once? The psychogenesis of epilepsy finds little support in modern textbooks. Epilepsy is essentially a neurological condition of neuronie derivation. Psychisms may be present however and influence the production of motor fits in any particular case, but they cannot be said to be *per se* the cause of them. A peculiar syndrome that has been for want of a better term misnamed hystero-epilepsy presupposes a combination of the factors of both epilepsy and hysteria. Another peculiar condition that is often described in conjunction with epilepsy is narcolepsy, because of the close similarity to *petit mal* for which it may be mistaken. The late Dr. Adie, however, clearly showed that narcolepsy is a disease *sui generis*.

Another peculiarity sometimes noticeable in epilepsy is that it may appear suddenly, generally at puberty, in an individual whose family history is free from any neuropathic diathesis. Again, although the usual march of epilepsy is progressive there are rare cases where the condition suddenly stops for some unaccountable reason, sometimes after an acute illness.

Another disorder which closely resembles *petit mal* is pyknolepsy. Under the title of paraepilepsy, Vergara has included this disorder with other paroxysmal affections such as migraine, vaso-vagal attacks, and periodical crepuscular states.

The difference between pyknolepsy and *petit mal*, however, is that in the former we have a larger number of attacks, the absence of occasional major seizures, the lack of intellectual deterioration and a tendency to spontaneous cure, especially at puberty. Is it possible that the symptoms of *petit mal* and pyknolepsy may coexist, or that the border-line between these

states overlaps so that one state passes imperceptibly into the other?

The symptoms of the following case which closely resemble that of larval epilepsy are described to show their peculiar and indeterminate nature, and the doubt and indecision they may cause in diagnosis.

K. C., a Muslim boy of 13, was admitted on the 11th October, 1934, from jail, to which he was sent for hitting a woman on the head with an axe without provocation while she was asleep. While in prison he was certified as insane, as he was violent and aggressive, talked incoherently, was dirty and destructive, and used to knock his head against the wall and floor.

A year previous to this, he had struck a little child who died from the effects of the injury a month later.

The previous history is that at the age of 3 months he used to cry incessantly and suffered from 'fits'. At the age of 4 years he injured his head by a fall, after which he used to get fits twice daily. There is no history of epilepsy or psychoses in the family.

On admission, he was 4 feet in height and fairly well built but the genitalia were infantile. He has several scars on the occipital region of his skull, the result of frequent falls.

This region is abnormally shaped. On the right side, there is a slight depression and then

the occiput protrudes in a conical shape to the right. The scalp over this area is freely movable, and it feels boggy and oedematous as if there was fluid underneath. X-ray examination revealed no abnormality in the skull, except thickening of the lower part of the occipital bone. When pressure is applied to this part he feels pain, headache, and faints. These symptoms have now subsided and firm pressure on the skull causes no discomfort.

His intellect shows no deterioration, which one would expect in a boy with epilepsy from the age of 4. In fact he is very intelligent, and precocious. He talks quite sensibly, memory, orientation, perception and ideation are well preserved. Emotionally he is unstable. He is usually very affectionate and playful, but in the midst of this he will suddenly strike anyone nearby. He is extremely grateful for any gifts and soon after receiving them he may suddenly throw them away or strike the giver and then immediately prostrate himself and contritely crave forgiveness, knowing he has misbehaved. When asked to explain his conduct he states that he is more-or-less constantly worried by visual hallucinations of two black men whom he sees making grimaces at him and annoying him. Hence he tries to strike them and as he gets annoyed strikes anyone nearby. Another peculiarity is that the sight of a mirror, a pair of spectacles or any polished surface he sees induces a feeling of fear. This produces tachycardia and he says that glasses or a mirror accentuates the hallucination.

He assaults any one wearing glasses, but the impulse to strike is uncontrollable and is not vicious. His vision is normal and the optic discs reveal no abnormality. There are no physical signs of a cerebral neoplasm. Since admission he has had no major fits, but when told to walk slowly he gets sudden mild transient attacks of giddiness and falls backwards, striking his head on the ground, but never losing consciousness. When walking slowly, his head is bent forwards and his eyes are fixed on the ground, and then he suddenly stops and sways backwards, but immediately pulls himself together and walks on. These attacks of swaying can be checked by a sharp command from any one nearby and thus they resemble closely the cataplectic attacks seen in narcolepsy. On the other hand, the boy never falls when he runs fast and he enjoys sprinting along the verandahs or grounds at a rapid rate. He never falls while playing about with a football. He falls only when he walks slowly alone, and yet he has no Rhombergism, ataxia, or inco-ordination of his limbs. He is therefore afraid to walk alone and wants to be led by a servant lest he should fall. The impulse to strike others is lessened if any one holds his hand, but if the hallucinations are strong enough he will still make the attempt

A PRACTICAL WAY OF DEALING WITH ÆDES ÆGYPTI (STEGOMYIA FAS- CIATA) MOSQUITO BREEDING IN COUNTRY CRAFT

By F. D. BANA, M.B., M.R.C.S., D.P.H., D.T.M. & H., J.P.
Administrative Medical Officer, Bombay Port Trust,
Ballard Road, Bombay

Ædes ægypti, the potential carrier of yellow fever virus, is widely spread throughout Bombay as was pointed out by Colonel Covell, I.M.S., and reiterated in a recent report on the subject by Dr Mahtre, Malaria Officer of the Bombay Municipality. In the city itself its breeding places extend as far north as Mahim, to the south to Colaba, and to the west to Malabar Hill; it breeds in garden-water tubs, fountains, antiformicas, vases, and utensils for storing water, wherever the water is not emptied out at regular intervals, and it is specially prevalent in thickly-populated parts of the city such as Khetwadi, Girgaum and Chowpaty.

Attention was drawn as far back as 1910 to the danger of this common species of Bombay mosquito as a potential carrier of yellow fever, by Colonel Gordon Tucker, I.M.S. Once the virus can travel from the West Coast and hinterland of Africa to the East Coast and thence by speedier air transport to India, the ports of India likely to be infected will be the major ports of Karachi and Bombay and some of the recently-sprung-up Kathiawar ports and, to a lesser extent, Marmagoa and the ports lying along the south-western coast line of India.

This important matter must needs therefore receive the serious attention of the local authorities, the local and central governments and full power and authority must be granted to the first of these to enable them to deal effectively with all vessels, including steam and sailing ships, and aircraft coming from endemic centres of yellow fever.

About half the sailing vessels, lighters, *dhow*s, and other country craft that enter Bombay

(Continued from previous column)

which is a gesture at striking the terrifying figures he sees. When he is placid and playful, the presence of the hallucinations can be detected by the sudden rapidity of the heart and a change in his expression and temper. Cerebellar disorder may be ruled out by the absence of constant giddiness, reeling, inco-ordination, or *adiadokokinesis*.

The peculiar configuration of the skull at the occipital region may be responsible for some form of pressure there, resulting in the visual hallucinations and the falling backwards. Beyond that it is difficult to classify the case as either *petit mal* or *pyknolepsy*, and yet the symptoms are so closely related. Treatment which is purely empirical is of no avail.

harbour for local trade breed the *Ædes ægypti* in their drinking-water barrels or boxes. A survey of these made by me from 26th February to 13th April, 1935, shows that out of 898 country craft examined 458 were harbouring the larvæ of this mosquito. Apart from its potential danger, the bite of this mosquito is most annoying as testified by complaints from shipping personnel in the docks.

Prior to my taking over charge of the anti-malaria and anti-mosquito work in the docks and bunders of Bombay, nothing had been done to mitigate this nuisance from country craft owing to the lack of statutory power. I instituted a regular campaign to deal with the trouble and, in spite of the lack of statutory authority, I have by means of education and persuasion been successful in tackling the problem, as may be seen from the following figures:—

Country craft examined at Alexandra Dock,
Princess Dock, Victoria Dock and Sassoon,
Malet and Carnac bunders

	Number	Percentage
Examined	898	..
Found breeding <i>Ædes ægypti</i>	458	51
Emptied out	385	43
Refused examination ..	31	4.3
Refused emptying ..	69	7.6

It will be seen that rather more than half of these brought into the docks harbour larvæ of *Ædes ægypti* in their drinking-water receptacles which are often found teeming with them.

The procedure adopted to clear them has been as follows:—An overseer with a gang of coolies inspects a collection of country craft in a dock or bund; if the drinking water contains larvæ the number of the craft and the place where it came from is noted. The master or *tindal* of the vessel is given a notice to the effect that it is in his own interest as well as of the shipping and the docks that he should help in destroying the larvæ breeding in his drinking-water barrels or boxes. It may be mentioned that these receptacles are invariably of wood, have no draw-off tap, and no properly fitting lid. A native craft sometimes carries more than one of these barrels or boxes, while those coming from distant ports like Bhavnagar, Kutch, Mandvi and Marmagoa have square ones often of a capacity of 400 or more gallons. There is a small opening at the top whence water is taken in and drawn off for drinking purposes, at most covered up with a bit of rough plank, so that it is accessible to dirt of all sorts and is a suitable place for the mosquito to lay its eggs.

Water has been usually procured in their native places or ports from wells or rivers near the bunders along which the country craft call for cargo. They are never emptied out thoroughly but water is added as required at every bunder or port of call. The larvæ of *stegomyia* are often found on the surface, if breeding is excessive, and from the bottom invariably, on scouring it. The overseer then explains to the master or *tindal* that it is necessary for the drinking water to be emptied out, the barrel or box thoroughly scoured, dried, and then refilled with fresh water. If he voluntarily complies with this, he is given a pass or certificate for free supply of water from the docks or the bunders.

So far this procedure has worked well as can be seen from the above figures, as many as 86 per cent of those showing breeding adopt this procedure and empty out the infested barrels. About 4 per cent refuse inspection, which is not compulsory, and about 7 per cent refuse to empty out usually because they have their tanks full and are in a hurry to sail, having taken fresh water recently without thoroughly emptying out the bottom of the tanks.

The following powers will have to be obtained in dealing with this problem when a proper local sanitary authority is created.

1. Right of inspection.

2. Right to insist on the provision of regulation mosquito-proof tank with proper fitting lid and a draw-off tap at the bottom. The tank to be certified by the registering authority at their respective bunders and ports and subject to periodical inspection and emptying out and cement washing.

3. Right to prosecute for non-compliance after preliminary notice or warning.

The various country craft or sailing vessels that call at Bombay hail from a long littoral, the Western coastboard of India; from Kutch, Mandvi, Bhavnagar, Okha, Broach, Surat, Bulsar, Billimora, Palghar, Bassin and Thana to the north and from Karanja, Ratnagiri, Goa, etc., to the south. The whole of the Western coast of India is more or less infested with this mosquito, and Bombay is far from being the only offender in this respect.

At present, the only solution lies in tackling its breeding grounds, and a preliminary effort has been made, as described above, to lessen the nuisance as far as possible, in the absence of statutory powers. The result has been that there are now less complaints from the areas treated than there were before.

My thanks are due to Mr. W. R. S. Sharpe, ex-chairman, Bombay Port Trust, and also to the Docks Manager and Deputy Conservator of the Port, for rendering all help in carrying out the above measures.

A NOTE ON AN UNUSUAL SOURCE OF CONTAMINATION OF WELL WATER

By RAO SAHIB T. N. S. RAGHAVACHARI, B.A.
Senior Public Health Assistant, King Institute,
Guindy

A DEEP well, intended to serve as a source of water supply for drinking and locomotive purposes, was constructed in 1931 at one of the west coast stations in South Kanara district. The water from this well was found to be of very fair quality for either purpose at the time of its construction and for some time thereafter. During the last twelve months, however, there has been a progressive deterioration in the æsthetic qualities of the water, although the chemical features had not appreciably changed since 1931. The water assumed a dirty brown colour and the sides of the brick wall of the steining in contact with water grew a dirty-green type of alga. In certain places the brick-work developed also a definite oily coating. The authorities concerned sent samples of the water and of the growths to the King Institute for examination and report. The results of the examination revealed nothing special that would account for the troubles complained of, and a questionnaire asking for detailed information on various points relating to the source and its location did not succeed in eliciting information of value.

At the request of the authorities concerned a local inspection and survey, accompanied by field tests, was recently carried out by the author. The well is a *pucca* built well with a perfect steining and with no evidence of any surface pollution entering through defective spots therein. The pump-house is located outside the well and the suction pipe entering the well was absolutely free from any trace of oil on it. No oil could enter the well from the pumps. There was a vague smell of petrol or kerosene in the atmosphere near the well. A sample of water drawn by means of a bucket smelt very definitely of petrol. Individual opinion of six different intelligent and unbiased observers confirmed the presence of the smell of petrol or kerosene.

A careful survey of the locality and surroundings of the well was next made. About 100 yards away from the site of the well the storage depot of a petroleum company has been built on a little mound about 15 feet high and has been in existence for a number of years. From careful enquiries made of the local agent of this depot, it was elicited that there was a considerable leakage of petrol from the underground tanks in this depot about 4 years ago. The agent also stated that when petrol leaks into the ground, it can remain there for a long time impregnating the soil, and find its way slowly into water sources laid in the area. The following note from a recent editorial in *Water and Water Engineering*, London, would appear to

lend weight to the theory that the well was probably being contaminated by the old leakage from the petrol tank.

'The water supply of Beverley has recently been unpleasantly but not injuriously affected by kerosene contamination from the gas works. Due to a leaking underground pipe-line carrying the kerosene oil from the main tank, the oil had percolated through the ground, impregnating the well area.

The trouble has now been righted by the Council's action in having the pipe, which was not a lead one, put overground. The contamination extended downwards a good many feet and may take some time to be eliminated from the soil'.

Dye tests were carried out, by introducing first uranin and then fluorescein, into a *nullah*

flowing within ten feet of the well. A dam was put up across this *nullah* and the dyes were added to the reservoir so formed. The well was subjected to vigorous pumping for the next 12 hours. The dye could not be detected in the well water. This negative finding could not, however, be accepted as significant, as the *nullah* was a shallow channel and as the feeder springs to the well might be from a different direction and at much lower depths.

Tests were then carried out to eliminate the colour, taste and odour in the water of this well. The addition of a grain each of alum and lime per gallon (the pH of the untreated water being 6.4) followed by the addition of 1 grain (per gallon) of powdered activated carbon and subsequent settlement for 3 hours resulted in the production of a perfectly æsthetic water suitable for drinking purposes.

A Mirror of Hospital Practice

INFECTION WITH *BERTIELLA STUDERI*

By P. A. MAPLESTONE, D.S.O., M.B., Ch.B., D.T.M.

(School of Tropical Medicine, Calcutta)

and

J. S. RIDDLE, M.B., Ch.B., D.T.M. & H.

MAJOR, I.M.S.

(District Laboratory, Lucknow)

THE patient, a European boy, aged five years, had two or three attacks of vomiting without apparent cause on the 29th October. He was given a dose of castor oil on the morning of the 30th and according to his mother passed a stool normal in appearance. About 2 a.m. on the 31st October the boy was seized with an acute attack of pain of a colicky nature, and although considerably relieved by a small dose of brandy he was brought to the British Military Hospital, Fyzabad, the same morning.

He was found to have slight abdominal pain but there was no tenderness. He was given a dose of magnesium sulphate mixture and shortly afterwards passed a stool containing a chain of tapeworm segments. That evening the temperature was 102.2°F. and there was slight abdominal pain and headache.

On the 1st November the temperature was normal and the patient passed several liquid stools after a further dose of magnesium sulphate, but no more worm segments were found.

On 2nd November the patient was given three doses of extract of male fern each of ten minims at seven, eight and nine a.m. respectively and the last dose was followed by a dose of magnesium sulphate mixture. No more tapeworm segments were passed and the boy was discharged from hospital the same day apparently quite well and he has remained well for over a month.

The abdominal symptoms were in all probability not referable to the tapeworm infection but were most likely caused by a moderately acute attack of gastro-enteritis of short duration such as children are commonly liable to, and the passage of part of a tapeworm was only a sequel to the brisk purgation to which the patient had been subjected.

The segments of the worm though somewhat decomposed stained well enough to enable their definite identification as those of a *Bertiella* sp. which according to the work of Adams and Webb (1933) is almost certainly *Bertiella studeri*.

Two cases of human infection with this parasite have previously been recorded in India, one by Chandler (1925) and the other by Maplestone (1930). Both these infected persons had lived in Eastern Bengal all their lives and were both Hindus. The present case is in a European child who during his residence in India has lived in Cawnpore for five months, Lucknow for two years and Fyzabad for one year, in that order. Other records of this parasite in human beings are from Mauritius four times, the West Indies twice and Sumatra once. It should be noted that Adams and Webb (1933) include a case reported by Mukerji (1927) but this is only a reference to the one recorded by Chandler, therefore the case of Adams (1935) is the ninth and the present one the tenth. In addition to the above ten cases in which either the whole or part of the worm was recovered Sharma (1930) claimed to have found the eggs of this worm in three stools out of 503 examined at Shillong.

A CASE OF THROMBO-ANGIITIS OBLITERANS TREATED BY FEMORAL PERI-ARTERIAL SYMPATHECTOMY

By MIN SEIN, M.B. (Cal.), M.R.C.P. (Lond.)
CAPTAIN, I.M.S.

Civil Surgeon, Bhamo, Burma

PERI-ARTERIAL sympathectomy for the treatment of thrombo-angiitis obliterans has to a large extent given place to the more severe operation of paravertebral ganglionectomy. The reason for this change is attributed to the uncertainty of or only temporary relief obtained by the minor operation. This is due to various causes of which two have been stressed. It has been proved by Stopford that the chief branches of the paravertebral ganglionic chains join the peripheral nerves and that they enter into the formation of the sympathetic sheath around the arteries at various levels along the course of the arteries. Thus peri-arterial decortication at any particular spot might miss the sympathetic fibres which are to be finally distributed to the terminal branches. Lambert Rogers demonstrated that the good effects produced by peri-arterial neurectomy are not permanent but last at the most five weeks. But there might still be cases where the vascular condition is of a minor degree and in which the lesser operation, if properly done, might afford permanent relief.

The following case has been described as an illustration. A point of interest to note is that the patient is a Chinese amongst whom the disease must be extremely rare, as I could not find any previous record by authorities I have consulted.

The patient, a Chinese male, aged 23, of Taungyi, Southern Shan States, Burma, was admitted into the Civil Hospital, Bhamo, on 3rd January, 1935, with the following complaints:—

Chronic progressive ulceration of the first, second, and big toes—in this order—of the left foot, duration about seven weeks. Severe pain in the toes, left foot and leg preventing sleep at night.

On 11th November, 1934, the first toe of the left foot was struck on the dorsum by a small stone, the size of a walnut, causing a small wound which bled a little at the time. There was no suppuration but the wound showed no tendency to heal. On the other hand the tip of the toe became black and the patient suffered from throbbing pain. He then undertook a seven days' journey to China on a pony. After the second day the whole foot became red and swollen up to the ankle and was so painful that he could not use the foot. The inguinal glands also became enlarged and painful. The condition did not show any improvement in spite of treatment by Chinese medicines. On the 12th or 13th December the toe received an accidental knock and the condition became much worse. A few days afterwards signs of gangrene appeared, e.g., the toe became black, was becoming dried up, with a sharp margin, and the pain was unbearable. The winter in Tengyueh (China) was very cold at night and very hot during the day. The cold made the pain worse and he could get no sleep at all. After a few days (20th December) a similar condition began to develop in the tip of the second toe. The condition progressed in both toes and on the 26th the big toe showed similar signs at the tip. He left China on the latter date and reached Bhamo on the 3rd January, 1935, when he came direct to the hospital for admission.

Personal history.—The patient was sensitive to cold. He is a teetotaller, smokes four or five cigarettes a day, and denies history of venereal disease. He has been married seven months.

Family history.—Father died when patient was 15; mother died when patient was two years of age. He has three sisters all of whom are healthy. There was no similar trouble in the family.

Condition on admission.—The patient looked worn out, there was no temperature and physical examination, apart from the local condition, was negative. The left foot was swollen and discoloured with a reddish-brown hue. The first toe showed signs of dry gangrene, the tip was shrivelled up, the whole toe was black and there was a line of demarcation a little below the metatarso-phalangeal joint. This line had cut through the skin and showed signs of sepsis. The terminal phalanx of the second toe was also in a similar condition though less advanced. There was a line of demarcation but the skin was intact. The big toe was black up to about the base of the nail where discoloration stopped with a sharp margin. All the parts were tender. There was no pulsation in the left dorsalis pedis artery and the left posterior tibial artery was hard and cord-like with very feeble pulsation behind the medial malleolus.

Treatment and further progress.—The part was kept dry by repeated application of methylated spirit over a dry dressing. Hot dry salt fomentation was applied to the foot.

The line of demarcation became more defined and dry and the first toe was amputated by disarticulating the metatarso-phalangeal joint on 7th January. The patient had to be given morphia every night because of the pain, but bromides had to be continued after the operation. The operation wound was slow in healing on account of the thickened and scaly condition of the skin. The second toe and the big toe showed signs of the progress of the disease and the pain in the second toe was also becoming worse. It was decided to try peri-arterial sympathectomy before doing anything further. Left femoral peri-arterial sympathectomy was performed under spinal anaesthesia on 19th January. The femoral artery appeared to be much smaller than usual, being only about the size of a normal radial artery. After giving off the profunda branch it became much attenuated. About two inches of the peri-arterial sheath was stripped off including as much of it as possible from the deep branch also. Within five days of the operation the patient complained that his left leg felt hot and that this was noticeable by him when he touched one leg with the other. The left leg and about three-quarters of the left thigh assumed a dusky colour from the second day. There was no noticeable difference in the temperature in the two limbs when taken with the thermometer in the popliteal space. Pain was relieved within a few days. Pulsation was felt in the posterior tibial and the dorsalis pedis arteries from the 24th January. The condition of the second and big toes improved steadily. By the 26th January there was no pain at all; the foot appeared normal except for the condition of the toes. It was noticed that the line of demarcation in the second and big toes had gradually receded towards the tips. Though it was thought that amputation of the terminal phalanx of the second toe might be necessary it was decided to wait a little longer. The subsequent improvement was so great that it was only necessary to remove the tip of the second toe on 23rd February which had by then dried up completely. The black area on the big toe also became smaller and only the skin and a little subcutaneous tissue were clipped off. The patient was discharged on 21st March but attended the outpatient department regularly. On enquiry at the time of writing (26th August, 1935) it was reported that the cure has so far been permanent.

PREGNANCY, WITH PARTIALLY OCCLUDED VAGINA

By J. F. HENRIQUES, L.M. & S., F.C.P. & S., B.M.S.

Officiating Civil Surgeon, Ratnagiri

A WOMAN, S. B., aged 25 years, married 6 years ago, was admitted into the hospital for retention of urine, the bladder being distended to within two inches of the epigastrium; the patient stated she had not passed urine for seven days, though probably this was not quite correct. She was treated at her village by applications of some irritants to the vulva, which was in a very swollen, septic and oedematous condition. The urine was drawn off; it amounted to 70 ounces. After the inflammation had subsided, a vaginal examination was done and no cervix could be felt, though her breasts showed the usual signs of pregnancy. One could feel, however, through the intervening partition, the outline of a distinct cervix. On introducing the

vaginal speculum, a thick septum was found about half-way up the vagina. It had only a small circular opening about two millimetres in diameter.

After the subsidence of the inflammation an incision was made through the septal opening and the vagina was thus made quite patent. The cervix had the usual signs of pregnancy and the uterus seemed to correspond to the size of a three months' pregnancy. It is interesting to note that pregnancy could occur in this case and that spermatozoa could pass through the small opening and subsequently through the external os. The septum was not tense and could, on vaginal examination before operation, be pushed up to the cervix by the finger. After the division of the septum, the vaginal passage seemed quite normal.

Previous history.—First menstruated at the age of eighteen years. Menstruation not painful, but regular and normal. Sexual intercourse was not painful.

Three months ago, that is about six years after marriage, she had cessation of menses and morning sickness for three months, and thought she was pregnant.

INTESTINAL TUBERCULOSIS

By Y. G. SHRIKHANDE, B.Sc., M.B., B.S., T.D.D. (Wales)
Acting Medical Superintendent, King Edward VII Sanatorium, Bhowali, U. P.

INFECTION of the alimentary tract may occur (1) by direct invasion of the lumen or (2) through the lymphatics or (3) by the blood stream.

Tuberculous ulceration of the intestine which occurs so frequently during the course of pulmonary tuberculosis is the result of direct infection from swallowed sputum containing tubercle bacilli. Infection by the blood stream is very rare but may occur in miliary tuberculosis. Animal experimentation has shown that hæmatogenous infection is followed by the development of tubercles in the walls of the alimentary tract. Such lesions should theoretically be isolated and widely scattered throughout the alimentary tract. In practical experience, however, this is not found in intestinal tuberculosis where the lesions are invariably found located in the vicinity of the ileocæcal region. Infection through the lymphatics may take place by local retrograde extension from tuberculous mesenteric glands and is, according to Stewart (1928), more common than is supposed. Cases are met with where with an advanced caseous glandular lesion lines of recent tuberculous lymphatics are seen extending to the gut and small recent ulcers are noticed within the latter. Stewart believes that the spread in these cases has been centrifugal and he accounts in this way for a localized group of ulcers high up in the ileum and jejunum with no evidence of lesions in the more usual sites.

Pathologically and clinically, however, there are only two important varieties of intestinal tuberculosis which may concern us here:—

(1) Primary, hyperplastic or proliferative type.

(2) Secondary or ulcerative type.

It may be mentioned here that by primary tuberculosis of the intestine it is understood that the intestinal mucous membrane is the portal of entry of the tubercle bacillus which passes through it without causing any apparent injury and no ulceration occurs at this stage. The first localization of the bacilli takes place in the mesenteric lymph nodes where tubercles are formed, causing sensitization of the body and serving as depots from which further dissemination can take place. Ulceration, on the other hand, is a manifestation of reinfection and it is therefore necessary that the focus of primary infection be established either in the intestinal lymphoid tissue or elsewhere before ulceration of the intestinal mucous membrane can take place.

Primary tuberculosis of the intestine

This is a comparatively rare type of tuberculous lesion which is essentially proliferative in character. Owing to the massive infiltration of all the coats of the intestine, a tumour is formed which may be indistinguishable clinically from any other granuloma or from malignant disease. Ulceration may or may not be present, and, if present, does not form a conspicuous feature of the disease. It is often impossible to be sure of the nature of the disease even after the operation until (a) several sections of the tumour and (b) neighbouring lymph glands are examined, or (c), with a negative histology, positive inoculation results are obtained.

The site of lesion is the ileocæcal region, the most frequent site being the cæcum, but the terminal ileum and the ascending colon may also be involved. Occasionally the appendix is also affected.

The important factors probably concerned in the explanation of this peculiar lesion are (a) a

A CASE OF THROMBO-ANGIITIS OBLITERANS TREATED BY FEMORAL PERI-ARTERIAL SYMPATHECTOMY

By MIN SEIN, M.B. (Cal.), M.R.C.P. (Lond.)
CAPTAIN, I.M.S.

Civil Surgeon, Bhamo, Burma

PERI-ARTERIAL sympathectomy for the treatment of thrombo-angiitis obliterans has to a large extent given place to the more severe operation of paravertebral ganglionectomy. The reason for this change is attributed to the uncertainty of or only temporary relief obtained by the minor operation. This is due to various causes of which two have been stressed. It has been proved by Stopford that the chief branches of the paravertebral ganglionic chains join the peripheral nerves and that they enter into the formation of the sympathetic sheath around the arteries at various levels along the course of the arteries. Thus peri-arterial decortication at any particular spot might miss the sympathetic fibres which are to be finally distributed to the terminal branches. Lambert Rogers demonstrated that the good effects produced by peri-arterial neurectomy are not permanent but last at the most five weeks. But there might still be cases where the vascular condition is of a minor degree and in which the lesser operation, if properly done, might afford permanent relief.

The following case has been described as an illustration. A point of interest to note is that the patient is a Chinese amongst whom the disease must be extremely rare, as I could not find any previous record by authorities I have consulted.

The patient, a Chinese male, aged 23, of Taungyi, Southern Shan States, Burma, was admitted into the Civil Hospital, Bhamo, on 3rd January, 1935, with the following complaints:—

Chronic progressive ulceration of the first, second, and big toes—in this order—of the left foot, duration about seven weeks. Severe pain in the toes, left foot and leg preventing sleep at night.

On 11th November, 1934, the first toe of the left foot was struck on the dorsum by a small stone, the size of a walnut, causing a small wound which bled a little at the time. There was no suppuration but the wound showed no tendency to heal. On the other hand the tip of the toe became black and the patient suffered from throbbing pain. He then undertook a seven days' journey to China on a pony. After the second day the whole foot became red and swollen up to the ankle and was so painful that he could not use the foot. The inguinal glands also became enlarged and painful. The condition did not show any improvement in spite of treatment by Chinese medicines. On the 12th or 13th December the toe received an accidental knock and the condition became much worse. A few days afterwards signs of gangrene appeared, *e.g.*, the toe became black, was becoming dried up, with a sharp margin, and the pain was unbearable. The winter in Tengyueh (China) was very cold at night and very hot during the day. The cold made the pain worse and he could get no sleep at all. After a few days (20th December) a similar condition began to develop in the tip of the second toe. The condition progressed in both toes and on the 26th the big toe showed similar signs at the tip. He left China on the latter date and reached Bhamo on the 3rd January, 1935, when he came direct to the hospital for admission.

Personal history.—The patient was sensitive to cold. He is a teetotaller, smokes four or five cigarettes a day, and denies history of venereal disease. He has been married seven months.

Family history.—Father died when patient was 15; mother died when patient was two years of age. He has three sisters all of whom are healthy. There was no similar trouble in the family.

Condition on admission.—The patient looked worn out, there was no temperature and physical examination, apart from the local condition, was negative. The left foot was swollen and discoloured with a reddish-brown hue. The first toe showed signs of dry gangrene, the tip was shrivelled up, the whole toe was black and there was a line of demarcation a little below the metatarso-phalangeal joint. This line had cut through the skin and showed signs of sepsis. The terminal phalanx of the second toe was also in a similar condition though less advanced. There was a line of demarcation but the skin was intact. The big toe was black up to about the base of the nail where discoloration stopped with a sharp margin. All the parts were tender. There was no pulsation in the left dorsalis pedis artery and the left posterior tibial artery was hard and cord-like with very feeble pulsation behind the medial malleolus.

Treatment and further progress.—The part was kept dry by repeated application of methylated spirit over a dry dressing. Hot dry salt fomentation was applied to the foot.

The line of demarcation became more defined and dry and the first toe was amputated by disarticulating the metatarso-phalangeal joint on 7th January. The patient had to be given morphia every night because of the pain, but bromides had to be continued after the operation. The operation wound was slow in healing on account of the thickened and scaly condition of the skin. The second toe and the big toe showed signs of the progress of the disease and the pain in the second toe was also becoming worse. It was decided to try peri-arterial sympathectomy before doing anything further. Left femoral peri-arterial sympathectomy was performed under spinal anaesthesia on 19th January. The femoral artery appeared to be much smaller than usual, being only about the size of a normal radial artery. After giving off the profunda branch it became much attenuated. About two inches of the peri-arterial sheath was stripped off including as much of it as possible from the deep branch also. Within five days of the operation the patient complained that his left leg felt hot and that this was noticeable by him when he touched one leg with the other. The left leg and about three-quarters of the left thigh assumed a dusky colour from the second day. There was no noticeable difference in the temperature in the two limbs when taken with the thermometer in the popliteal space. Pain was relieved within a few days. Pulsation was felt in the posterior tibial and the dorsalis pedis arteries from the 24th January. The condition of the second and big toes improved steadily. By the 26th January there was no pain at all; the foot appeared normal except for the condition of the toes. It was noticed that the line of demarcation in the second and big toes had gradually receded towards the tips. Though it was thought that amputation of the terminal phalanx of the second toe might be necessary it was decided to wait a little longer. The subsequent improvement was so great that it was only necessary to remove the tip of the second toe on 23rd February which had by then dried up completely. The black area on the big toe also became smaller and only the skin and a little subcutaneous tissue were clipped off. The patient was discharged on 21st March but attended the outpatient department regularly. On enquiry at the time of writing (26th August, 1935) it was reported that the cure has so far been permanent.

INTESTINAL TUBERCULOSIS

By Y. G. SHRIKHANDE, B.Sc., M.B., B.S., T.D.D. (Wales)
*Acting Medical Superintendent, King Edward VII
Sanatorium, Bhowali, U. P.*

INFECTION of the alimentary tract may occur (1) by direct invasion of the lumen or (2) through the lymphatics or (3) by the blood stream.

Tuberculous ulceration of the intestine which occurs so frequently during the course of pulmonary tuberculosis is the result of direct infection from swallowed sputum containing tubercle bacilli. Infection by the blood stream is very rare but may occur in miliary tuberculosis. Animal experimentation has shown that hæmatogenous infection is followed by the development of tubercles in the walls of the alimentary tract. Such lesions should theoretically be isolated and widely scattered throughout the alimentary tract. In practical experience, however, this is not found in intestinal tuberculosis where the lesions are invariably found located in the vicinity of the ileocæcal region. Infection through the lymphatics may take place by local retrograde extension from tuberculous mesenteric glands and is, according to Stewart (1928), more common than is supposed. Cases are met with where with an advanced caseous glandular lesion lines of recent tuberculous lymphatics are seen extending to the gut and small recent ulcers are noticed within the latter. Stewart believes that the spread in these cases has been centrifugal and he accounts in this way for a localized group of ulcers high up in the ileum and jejunum with no evidence of lesions in the more usual sites.

Pathologically and clinically, however, there are only two important varieties of intestinal tuberculosis which may concern us here:—

(1) Primary, hyperplastic or proliferative type.

(2) Secondary or ulcerative type.

It may be mentioned here that by primary tuberculosis of the intestine it is understood that the intestinal mucous membrane is the portal of entry of the tubercle bacillus which passes through it without causing any apparent injury and no ulceration occurs at this stage. The first localization of the bacilli takes place in the mesenteric lymph nodes where tubercles are formed, causing sensitization of the body and serving as depots from which further dissemination can take place. Ulceration, on the other hand, is a manifestation of reinfection and it is therefore necessary that the focus of primary infection be established either in the intestinal lymphoid tissue or elsewhere before ulceration of the intestinal mucous membrane can take place.

Primary tuberculosis of the intestine

This is a comparatively rare type of tuberculous lesion which is essentially proliferative in character. Owing to the massive infiltration of all the coats of the intestine, a tumour is formed which may be indistinguishable clinically from any other granuloma or from malignant disease. Ulceration may or may not be present, and, if present, does not form a conspicuous feature of the disease. It is often impossible to be sure of the nature of the disease even after the operation until (a) several sections of the tumour and (b) neighbouring lymph glands are examined, or (c), with a negative histology, positive inoculation results are obtained.

The site of lesion is the ileocæcal region, the most frequent site being the cæcum, but the terminal ileum and the ascending colon may also be involved. Occasionally the appendix is also affected.

The important factors probably concerned in the explanation of this peculiar lesion are (a) a

fairly high grade immunity to tuberculous infection, (b) infection by a small number of bacilli and (c) infection by bacilli of low virulence, in many cases bovine in origin.

Two important phenomena are associated with the condition, namely (a) a large tumour is palpable in the cæcal region and (b) signs of chronic intestinal obstruction manifest themselves. The treatment consists in resection, or a short-circuiting operation.

The disease is said to be fairly prevalent in Europe and less so in America. It is rare in India probably because bovine tuberculosis, as has been pointed out by Lankester (1920), is not common in this country and milk which is the main source of the bovine bacillus is not taken raw. Further, judging from the universal and abominable habit of spitting anywhere and everywhere which is so prevalent in this country, the human bacillus would appear to be the commonest source of infection and intestinal tuberculosis is therefore found to occur as a common complication of and secondary to the disease in the lungs.

Secondary intestinal tuberculosis

This is a very common complication of pulmonary tuberculosis and is the result of swallowing sputum consciously or unconsciously. Calmette (1923), however, believes that the constant elimination of the bacilli in the bile may also furnish the source of infection to the intestinal tract.

Secondary tuberculosis of the intestine is a manifestation of Koch's phenomenon and is, therefore, frankly ulcerative. Owing to the sensitization of the body that has already taken place by the presence of the disease in the lungs, the chief struggle for mastery has now been transferred from the regional lymph nodes with which the body is naturally endowed, to the cells of the mucous membrane of the intestinal tract on which has been conferred the specific defensive rôle as a result of the primary infection in the lungs. There is not much reactive fibrosis and the muscular coat is rarely penetrated completely in this type. Intraperitoneal perforation is uncommon owing to the formation of adhesions between the coils of the intestine. In contradistinction to the hyperplastic type, this variety rarely gives rise to any serious obstruction partly due to the destructive character of the lesion and partly because the patient usually dies before cicatrization can take place to any appreciable extent.

Site of lesion

The most frequent site of affection is the ileo-cæcal region—the terminal part of the ileum, the cæcum and the first part of the ascending colon. The probable reasons for this are:—

(a) Tuberculous disease first attacks the lymphoid tissue and this in the form of solitary

follicles and Peyer's patches is abundant in the terminal part of the ileum.

(b) Absorption of the last products of digestion takes place in the terminal ileum and the infected material comes in direct contact with the mucous membrane.

(c) The bowel contents remain for quite a long time in the ileo-cæcal region thus giving opportunity to the bacilli to cause infection in this region.

It is well to bear in mind that the lower portion of the ileum, the cæcum and the ascending colon have two points in common. Each represents the part of their portions of the digestive tract where slowness of the passage of contents and absorptive activity are most pronounced.

Pottenger (1922) has suggested the possibility of trophic disturbances in the cells of the intestinal wall brought about by prolonged stimulation of the sympathetic and vagus nervous system which lower their resistance to infection.

It is interesting to mention here that tuberculous ulceration of the intestine spreads at right angles to the long axis of the bowel in contrast to the ulceration of typhoid fever. The reason is that tuberculous infection spreads along the course of the lymphatics which run around instead of lengthwise of the intestine.

The problem of secondary intestinal tuberculosis is exactly what the problem of pulmonary tuberculosis was some fifty years ago; its onset meant the rapid termination of the life of the patient. This view-point may hold good even to-day if we were to wait for its diagnosis until the classical symptoms like tenderness and pain, diarrhoea and emaciation manifest themselves. These are not early diagnostic signs but late prognostic omens. They should be considered as late signs of intestinal ulceration, just as bubbling râles and cavities are of pulmonary tuberculosis. If we are not aware of this complication until these late symptoms have been established we are no wiser than our forefathers and the outlook must still remain hopeless. For here, as in pulmonary tuberculosis, the diagnosis to be of any value must be made early and to make an early diagnosis we must consider what may be called the border-line symptoms.

It would be fortunate if there was any pathognomonic sign of intestinal tuberculosis, but unfortunately there is none. The symptom-complex is not constant; in fact, it is quite variable. One may have violent cramps, another only abdominal consciousness; one may have diarrhoea, another constipation; one may have anorexia, another good appetite.

Moreover, some of the gastro-intestinal disturbances may be due to causes other than tuberculous ulceration. (a) They may, for instance, be due to the sedentary life and generous diet employed in the treatment of pulmonary tuberculosis. Over-feeding and other errors in diet

may be responsible for dyspepsia or an inactive life for constipation. The unfortunate tuberculous patient must be pardoned if he suffers from ills not necessarily tuberculous in nature. Davies (1922) has shown that intestinal stasis not infrequently gives rise to gastro-intestinal disturbances and is brought about by the decomposition of foodstuffs and the production of amino-acid derivatives. (b) Diarrhoea may be due to the insufficiency of digestive glands or to the administration of certain drugs for treatment. (c) Amyloid disease of the intestine may cause digestive disturbances particularly diarrhoea. (d) Digestive disturbances may also be due to the toxæmia of pulmonary tuberculosis or be 'reflex' in origin and produced, as shown by Pottenger (1922), by the stimulation of the peripheral ends of the sympathetic and vagus systems.

But all said and done, intestinal ulceration remains the sinister complication of pulmonary tuberculosis and the fight is often fought and won or lost not so much in the lung as on the gastro-intestinal front. Old sayings like 'stomach is the greatest friend of the consumptive' or 'poor eaters do badly' or 'a flux of the bowel leads to a fatal outcome' have apparently been coined to stress the importance of the alimentary tract in the treatment of pulmonary tuberculosis.

Symptoms

The earlier symptoms of intestinal tuberculosis are generally due to lesions in the small bowel; the later to lesions in the large bowel. Ulceration in the small bowel tends to retard the passage; in the large bowel to accelerate it. The earlier symptoms are gradual and slight change from the patient's normal temperament towards nervousness and irritability; from usual and normal appetite towards slight impairment and from usual bowel habit towards constipation. Nervousness, slight impairment of appetite and constipation beyond usual form, therefore, are the early and most useful diagnostic triad. An ulcer in the small intestine produces spasm and it is to this spasm that the earlier symptoms are due. Later, when the large intestine also gets involved diarrhoea with foul-smelling stools results. Constipation is thus a special feature of ulceration in the small bowel while diarrhoea is a symptom of ulceration in the large bowel. Alternating constipation and diarrhoea indicate ulceration in both the tracts.

In order to understand the symptom-complex of intestinal tuberculosis it must be borne in mind that the underlying pathology is an ulcerative enterocolitis. The physiological response to ulceration is increased irritability of the bowel. This increased irritability is manifested by hypermotility. In the small intestine, moreover, ulceration produces spasm. Hence constipation and diarrhoea become important factors. The stools are soft and unformed,

often liquid and may contain mucus, blood or pus.

With ulceration of the intestines comes peritoneal irritation and this results in abdominal pain, abdominal tenderness and abdominal rigidity. The pain tends to come on shortly after eating and may be colicky in character. Tenderness is first noticed over the ileocaecal region and later over the whole abdomen. Similarly, rigidity commences in the right iliac fossa and spreads over the entire abdomen. The mesenteric glands may be palpable in the right iliac fossa or round about the umbilicus. While it is generally true that secondary tuberculous involvement is not accompanied by the enlargement of the regional lymph nodes, this rule does not hold if the infection is sufficiently severe. For this reason the mesenteric lymph glands are sometimes found to be enlarged and even caseous.

As a consequence of the ulcerative enterocolitis certain constitutional signs and symptoms result, such as slight elevation of temperature without any increase in the pulmonary symptoms or failure to improve and gain in weight when the pulmonary lesion is quiescent or shows signs of improvement. Not infrequently the regular curve of temperature in pulmonary tuberculosis becomes irregular and varies from day to day—becomes regularly irregular, if it may be so described. Digestive symptoms also appear such as nausea, vomiting, flatulence, discomfort and change in the bowel habit; for example, a patient who has been constipated shows an increased frequency of stools or a patient who has had normal bowels becomes constipated. In the opinion of Bandelier and Roepke (1913), diarrhoea occurring at night in phthisical patients is very suggestive of intestinal tuberculosis. Owing to the increased irritability of the intestine the food taken early in the day is discharged in the night and the movements continue during the day.

Diagnosis

The methods of diagnosis of intestinal tuberculosis may be discussed under three headings—(a) clinical, (b) laboratory, and (c) radiological.

(a) *Clinical diagnosis.*—The outstanding signs and symptoms have already been mentioned. One thing must be emphasized, namely, the earliest symptoms must be anticipated. There is a wide difference between the normal digestive functions of even healthy persons. Small disturbances in these may easily, therefore, be attributed to lapses on the part of persons from their normal diets and when brought about in patients by tuberculous ulceration of the intestine are considered to be due to a lack of control of the palate. The patient, therefore, fights shy of mentioning them to his physician until they are well established. It is up to the physician and not the patient to be on

the look out for them to make a diagnosis. Similarly, slight deviation from normal temperament towards nervous irritability is attributed to lapses in self-control. When a patient who is usually placid begins to get irritable, nervous and querulous, the physician must think of intestinal tuberculosis as a likely cause. It is an old dictum that disease above the diaphragm makes a patient optimistic while disease below it makes him pessimistic.

(b) *Laboratory diagnosis.*—The laboratory diagnosis of intestinal tuberculosis is notoriously uncertain. The presence of tubercle bacilli in stools is not proof positive of intestinal ulceration in the presence of active pulmonary tuberculosis. The sputum may be swallowed consciously or unconsciously. Women are the worst culprits in this respect. They swallow the sputum deliberately either from indolence or from an aversion to the spitting flask. The presence of pus and blood in stools is presumptive evidence when the patient is suffering from pulmonary tuberculosis and gastro-intestinal symptoms are present. Occult blood when found is a fairly strong evidence but need not be a constant finding. The Triboulet test which indicates the finding of soluble 'allevium' in the faeces has not been found to be specific for ulceration of the intestine. The blood picture usually shows a moderate amount of leucocytosis but this may be due also to the presence of a cavity in the lung. The tuberculin test may cause some increase of abdominal pain but aids little in diagnosis.

(c) *Radiological diagnosis.*—The first worker to use the radiological method in the diagnosis of intestinal tuberculosis was Stierling (Brown and Sampson, 1930) who, in 1911, showed that in ulceration of the ileocaecal region the opaque meal is hurried over this portion of the gut throwing little or no shadow on the film six or seven hours following the ingestion of the meal. Pirie (Brown and Sampson, 1930) in 1917 recorded somewhat similar findings. But no serious attention was given to this method of diagnosis until in 1919 Brown and Sampson (1930) worked out this method of diagnosis by x-raying the alimentary tracts of all patients in the Trudeau Sanatorium.

In this method of diagnosis fluoroscopic observations are made every half-hour or so from the seventh to the tenth hour following the ingestion of the barium meal and finally at the twenty-fourth hour. The patient is instructed not to use any laxative for thirty-six hours prior to the ingestion of the barium meal in order to exclude the possibility of any hypermotility from its use and he is also advised to abstain from eating or drinking anything in the interval between the barium meal ingestion and the first fluoroscopic observation to enable one to estimate the emptying time of the stomach. The barium enema may be given a day or two later to confirm the barium meal findings but is not

absolutely necessary. Films are usually taken when there is most to record, namely, at the seventh, tenth and twenty-fourth hours.

It has already been shown above, that pathologically the caecum and ascending colon form the chief storm-centres of ulceration, at least as far as the large bowel is concerned. A well-rounded smooth-walled caecum still fairly filled after 24 hours with the tail of the meal gives a normal barium appearance to establish a negative diagnosis. On the other hand, a ragged, dwarfed, shrivelled caecum, or a caecum that does not fill or shows filling defects or that empties quickly and seems intolerant of barium nearly decides the diagnosis. Variations at the right or ascending side of the large bowel are more significant than at the left or descending side. Gastric retention suggests irritation lower down in the small intestine. Segmentation in the lower part of the ileum suggests damming due to ulceration and consequent spasm.

The findings of Brown and Sampson may be summarized as follows:—

(a) General hypermotility with complete or nearly complete emptying of the colon in 24 hours.

(b) Failure of the caecum or of the ascending colon and hepatic flexure to retain the barium.

(c) The presence of spasm or spastic filling defects, irregular contour and absence of haustrations in the ascending colon.

(d) Segmentation of the coil of small intestine with or without dilatation of the coils.

(e) Ileal stasis and gastric retention.

It is important to remember that these findings indicate only the presence and not the nature of ulceration. While hypermotility may be present in other conditions also, its combination with filling defects confirms the presence of ulcerative condition of the intestine. In the presence of active pulmonary tuberculosis the tuberculous nature of these ulcers may be inferred with some degree of certainty. Moreover, other types of ulceration do not occur primarily in the ileocaecal region. The absence of hypermotility and filling defects excludes for practical purposes the presence of tuberculous colitis, unless of course the condition has already healed up.

Differential diagnosis.—Since the direct diagnosis of intestinal tuberculosis is based on the evidence of hypermotility of the intestinal tract, mistakes are likely to be made and the differential diagnosis must be made from other pathological conditions which give the same results. Gauss, Singerman and Black (1933) have discussed the differential diagnosis from the following conditions:—(1) protozoal infections, (2) bacterial infection of the colon, (3) tumours of the intestine, (4) disorders on the formation, position and configuration of the colon, (5) subacute and chronic appendicitis, (6) digestive disorders like achylia gastrica, or

pancreatic insufficiency, (7) nutritional disorders like pernicious anæmia or pellagra, (8) blood dyscrasias like myelogenous leukæmia, (9) endocrine disorders like hyperthyroidism or Addison's disease, (10) cardio-renal disease, (11) industrial poisons like lead and arsenic, (12) surgical complications like nephrectomy or adhesions and (13) rectal disorders like proctitis and fissures.

A careful consideration of the clinical features together with the x-ray findings and other necessary tests will, in most cases, differentiate the above conditions from intestinal tuberculosis.

The importance of x-ray in the diagnosis of intestinal tuberculosis cannot be denied. In a proverbially poor country like India, however, the radiological method of diagnosis cannot be employed as a routine measure for the simple reason that it is too expensive for the average patient. Moreover, there are still few facilities for x-ray in this country. This does not mean that x-ray should not be employed wherever it is possible to do so, but considering everything greater importance should be attached to physical signs and symptoms.

Treatment

General measures.—As soon as the diagnosis of intestinal tuberculosis is made, certain general principles must be observed. The patient should be told to rest in bed as exercise may stimulate the peristaltic movements of the bowels. The rest should be continued as long as active bowel symptoms are present and for some time after. If the lung lesion is active a serious attempt should be made to bring about a successful control of the pulmonary condition to obviate the possibility of reinfection of the intestinal tract from this source. The patient should be advised to use constantly an abdominal binder covering the whole of the abdomen. This keeps the abdomen warm and protects it from catching chill. Similarly, chilling of the feet should be avoided as it has also been found to act adversely.

Dietetic treatment.—Tuberculous intestine, like any other organ affected by the disease, requires rest. It has been found that in patients who have an irritable bowel the mere act of eating produces reflex peristalsis of the terminal ileum and colon, quite independently of the nature of food taken. Distension of the bowel tends to stimulate the peristaltic movements: consequently food that causes fermentation such as peas, beans, cabbages, potatoes, should be excluded. Milk also causes flatulent distension and diarrhœa in some patients and has to be stopped. Experience has shown that raw eggs sometimes give rise to loose motions. Raw white of the egg is not digested easily and has been found experimentally to stimulate only partly the flow of the gastric juice. On the other hand, cooked white of the egg is easily digested and

well utilized by the economy. In the opinion of Fishberg (1922), as long as eggs are not consumed raw they make an excellent food for the tuberculous patient. Foods which leave a good deal of residue in the bowel irritate the ulcerated mucous membrane and cause diarrhœa; such foods should be stopped. Alvarez (Brown and Sampson, 1930) has advocated the smooth, cellulose-free diet which aims at supplying the necessary nourishment with the least amount of work and irritation to the intestine. It is small in bulk, high in caloric value, fairly varied, easily prepared, palatable and easily assimilated. With cellulose mainly removed the starches are acted upon more freely. If bulk is needed agar can be added. It seems to lessen flatulence, discomfort and bowel irregularities. Lean meat is the basis of the diet.

In a vast country like India, the selection of diet for a consumptive is a very difficult problem indeed. Normal diets vary with different provinces and many are strictly vegetarians. It is well known that the proteins of vegetable origin are not easily assimilated and vegetable food leaves a great deal of residue behind which stimulates peristalsis.

Lassabliere (1922) has recommended a diet exclusively of sweetened condensed milk diluted with four parts of rice water of which a teacupful is taken every two or three hours, one or two litres being taken in 24 hours. No other food, liquid or solid, has to be taken. The number of stools are said to be reduced in two or three days after which other ingredients may be added gradually to the diet.

Morriss (1924) has found bacillus-acidophilus milk treatment first described by Rettger and Chaplin of great therapeutic value. He has given one pint of milk with 50 grammes of lactose daily with satisfactory results. Sufficient care has to be taken in regulating the quantity of milk and of lactose. In India, sour milk, in the form of dahi, butter-milk, etc., has been used extensively from time immemorial and proves satisfactory where pure milk does not agree with the patient. Bernard Fantus (1934) has described the raw apple diet for diarrhœa. Thoroughly ripe apples are converted into a pulp and taken raw—1 to 4 tablespoonfuls being taken every hour or two for 48 hours, during which period no other food or medicine is taken. Banana pulp may be added if the apple pulp alone is refused. This is followed by a transitional diet consisting of soup, cooked cereal without milk, toast, potato gruel, cocoa or tea without milk, etc., for another 48 hours, after which milk, vegetables and fruits are added to the diet. The pectin content of the apple is supposed to form a colloidal absorbent mass which absorbs the toxins and the amines and produces good results.

Heliotherapy.—Heliotherapy has been used successfully for several years by Rollier (1927)

in the treatment of surgical tuberculosis. Its value in the treatment of intestinal tuberculosis could not be established as long as no definite method of diagnosis was known in order to decide when the disease in the bowel began or whether or not it was at all present. The *x*-ray method of diagnosis has, however, made it possible to employ heliotherapy in the treatment of intestinal tuberculosis. Heliotherapy may be natural or artificial; the latter is preferable because it contains pure ultra-violet rays while with the former are associated the luminous rays also. For artificial heliotherapy the carbon-arc lamp or mercury-vapour lamp may be employed. The mercury-vapour lamp is, however, simpler to use and can be controlled by the patient himself. Advantage must, of course, be taken of the sun's rays in the absence of an ultra-violet ray lamp.

Limited areas of skin are first exposed to the ultra-violet rays for short periods and then the time of exposures and the extent of the skin exposed are gradually increased in order to avoid severe local or general reactions. It is said that patients whose skin becomes pigmented easily have a better prognosis. The results of treatment by heliotherapy have been reported to be quite satisfactory. Pain, nausea and vomiting are quickly relieved but diarrhoea and digestive disturbances take some time. Better results are said to be obtained when the treatment is commenced soon after the symptoms manifest themselves.

When the desired results are not obtained by heliotherapy, *x*-ray treatment of the intestinal tract has been advocated. Great care has however to be taken in the use of *x*-ray as it has been shown experimentally that the intestinal mucous membrane is very susceptible to hard and short *x*-rays.

Tomato juice and cod-liver oil treatment.—During his trip to America in 1930, the writer (1931) was much impressed to find that tomato juice and cod-liver oil were being employed on a very large scale. This method of treatment is the result of experiments carried out by McConkey (1930) who discovered that it was necessary to have a deficiency of vitamin C in diet in order to produce intestinal tuberculosis in experimental animals. McConkey thought that since heliotherapy and cod-liver oil are equally efficacious in the treatment of rickets and since intestinal tuberculosis can be treated successfully by heliotherapy, it was not unreasonable to expect equally good results from the use of cod-liver oil. Cod-liver oil alone has an unpleasant taste and upsets many patients, but the combination of tomato or orange juice with the oil gave better results. McConkey believes that the treatment affects some change in the calcium metabolism which brings about immediate relief of symptoms and the healing of ulcers. The treatment is very simple—half an ounce of cod-liver oil in three ounces of fresh

tomato juice is taken three times a day immediately after the principal meals. An average-sized orange may be substituted for tomato juice. According to McConkey, this treatment is more economical than artificial heliotherapy and may also prove a means of preventing intestinal tuberculosis in pulmonary cases. As we know, cod liver contains vitamins A and D and tomato or orange juice contains vitamin C. The treatment is, therefore, a simple high vitamin diet treatment. Our experience with this method of treatment has, however, not proved very encouraging perhaps because the patients treated with it were already on a diet rich in fresh vegetable produce and fatty material.

Medicinal treatment.—Drugs of almost every kind have been used in the treatment of intestinal tuberculosis, such as, antiseptics, astringents, sedatives, and opiates, but they have been used more for the relief of symptoms than for the cure of the disease. The list of these drugs is very long and is ever increasing, but the fact that we have a thousand and one remedies speaks more loudly than words for their failure as a 'cure'.

Jacquelin (1924) has described certain simple procedures such as reaction to litmus paper, time taken for food to pass through the alimentary tract, microscopical examination of stools, etc., in order to determine the type of enteritis present and to treat the condition accordingly. He has classified diarrhoea into four groups requiring different methods of treatment:—

(1) *Simple enteritis* accompanied by fever and coated tongue. Treated by dieting, gentle saline purgation and intestinal antiseptics, especially lactic ferments. Treatment not to be kept longer than is absolutely necessary.

(2) *Diarrhoea associated with hyper-functioning of stomach, liver and pancreas* best treated by pepsin, pancreatin and sodium bicarbonate at meal times and small doses of hydrochloric acid after meals. At other times powdered charcoal, prepared chalk and powdered nuxvomica may be taken.

(3) *Putrefactive or fermentative diarrhoea* treated by lessening the intake of carbohydrates and of meat and eggs.

(4) *Ulcerative enteritis* characterized with abdominal pain, the presence of blood, albumin in the stools and by its intractable character. This is the tuberculous type of enteritis and is treated with antiseptics, astringents, sedatives, kaolin, calcium chloride injections, opium, etc.

Treatment of important symptoms

(1) *Diarrhoea.*—(a) Calcium chloride has been used extensively and is best given by the intravenous route. The usual dose is 5 c.cm. of a 5 per cent solution, given once or twice a week, but it may be used more frequently and in greater concentration according to the necessity of the case. It is believed that calcium

chloride acts on the vegetative nervous system and decreases the peristaltic movements by reducing the irritability of the smooth muscle of the intestinal wall and thus gives rest to the affected part. It also gives relief to pain and bleeding.

(b) *Castor oil* yields good results in some cases. Davies (1922) has spoken of the 'charm' of castor oil in the treatment of intestinal stasis. Sodium ricinoleate has been used in place of castor oil with better results, probably because it is free from disagreeable and nauseating taste and is therefore capable of being administered for as long a time as desired. It maintains the normal intestinal gradient, reduces toxæmia and relieves symptoms without producing unnecessary purgation.

(c) *Bismuth and astringents and their combinations* have been used. Substances containing tannic acid usually affect the stomach slightly, but with the alkaline reaction of the intestine, they precipitate the proteins and so protect the mucous membrane which is thus less stimulated and peristalsis is lessened. The mucus may be reduced and fermentation hindered.

(d) *Certain inert powders*, like animal charcoal and kaolin, are prescribed for coating and protecting the mucous membrane and for the absorption of gases.

(e) *Antiseptics*, like creosote, iodoform, dimol, benzonaphthol, methylene blue, have all been used.

(f) *Opiates* are resorted to when other remedies fail in checking diarrhoea.

(g) *Enemata*, either of saline alone or combined with tincture of opium or one of the silver preparations, have been found to give relief in some cases. Starch and opium enema may have to be tried. It must not be forgotten that many patients feel better when the bowels are loose.

(2) *Constipation*.—Liquid paraffin, castor oil and other mild laxatives are used. Several patent medicines, like paragol, petromol, petrolagar, are available in the market. Kaylene-ol, a combination of kaolin and liquid paraffin, has been found to be very useful in the writer's experience.

(3) *Pain*.—Calcium chloride injections are supposed to give relief. If pain persists, hot fomentations, hot wet compresses, turpentine stupes, antiphlogistine, etc., may be applied externally over the abdomen. Internally, benzyl-benzoate, atropine, opium may be given. Ispaghula has been found to give great relief to intestinal symptoms and is used extensively in this country. Spigel seeds contain, as we know, much mucilage and are given in the form of cool demulcent drinks for pain and diarrhoea.

Surgical treatment.—Surgery has a very limited field in the treatment of secondary tuberculosis of the intestine. For the operation

to be of any value the ulceration must be confined to a limited area so that the diseased portion of the bowel may be excised with some hope of success. Short-circuiting operations have been tried but not with any great success.

The injection of oxygen in the peritoneal cavity has been advocated and satisfactory results reported. The technique is practically the same as that employed for artificial pneumothorax. McBurney's point is selected for the injection and 300 to 500 c.cm. of oxygen are injected after anaesthetizing the needle tract, including the peritoneum, with novocain solution. The intervals between the injections vary from one to three weeks depending upon the condition of the patient.

Prognosis

The occurrence of persistent diarrhoea in a phthisical patient has always been regarded as of grave significance. The old Hippocratic saying 'diarrhoea attacking a person with phthisis is a mortal symptom' has been held valid until very recently. Autopsy figures show that intestinal tuberculosis occurs in from 50 to 80 per cent or even more of all cases of pulmonary tuberculosis. It has been estimated by Drolet (Brown and Sampson, 1930) that about 18,000,000 patients have died from pulmonary tuberculosis throughout the world during forty years; of this number, from 9,000,000 to 14,000,000 had intestinal tuberculosis. It is doubtful if these figures include the mortality figures from India where no reliable and accurate statistics are available and the mortality from pulmonary and intestinal tuberculosis must necessarily be very great. Intestinal ulceration would appear to be more common and more severe in Indian patients because the people of this country have not yet developed that amount of racial immunity which people in the West have done. The prognosis is, therefore, more serious in Indian patients.

The prognosis of intestinal tuberculosis is determined by the character of the disease in the lungs; in other words, the amount of tuberculous enteritis is directly proportional to the degree of activity in the lungs. It has been found that healing in the intestine is much more frequent in the productive type of pulmonary tuberculosis than is the case in the exudative form. The explanation for this probably lies in the fact that the intestine reacts slightly or vigorously in proportion to the number of tubercle bacilli swallowed with the sputum and this factor is largely governed by the character of the pulmonary lesion. It will thus appear that factors like the number of bacilli swallowed with the sputum, the condition of the patient and his vitamin balance in the diet are controlling factors in the production of intestinal tuberculosis.

If the diagnosis of intestinal tuberculosis were made in good time, if the general condition of

the patient is good and if the pulmonary condition is not in an advanced stage and if the patient is placed under proper and prolonged treatment at this time, the prognosis would be brighter. Tuberculous lungs heal; tuberculous lesions of the intestine tend also to heal and can be shown by barium meal to have healed. At the same time, the difficulty which attends the healing of severe widespread infection in the intestinal wall, particularly when frank ulceration has taken place, must be quite evident. The surface of the ulcers is constantly bathed in irritating mixtures of digestive juices and food in various stages of digestion which produce more or less maceration of the tissues and retard healing. When, therefore, the ulceration is widespread and the pulmonary condition is far advanced and the general condition of the patient is poor, little can be hoped for except amelioration of the symptoms. In such cases the intestinal lesion only hastens the inevitable end. The prognosis of intestinal tuberculosis, therefore, depends, as in pulmonary tuberculosis, upon early diagnosis and proper treatment. We are still making the diagnosis at a late stage. By methods we now have at our command we can make it much earlier and if we do this there is no reason why intestinal tuberculosis should not yield to treatment just as pulmonary lesions do.

Prevention

'Prevention is better than cure' is an old adage which is nowhere so true as in intestinal tuberculosis. The prevention of intestinal tuberculosis depends upon the early diagnosis and treatment of pulmonary tuberculosis. Patients should be warned against swallowing the sputum, which they do from ignorance, from indolence, or from aversion to the spitting flask, as this is the chief source of infection of the intestinal tract. When one remembers that no matter how great the care taken patients, suffering from open lesions in the lung, swallow bacillus-bearing sputum daily and often in large quantities, the relatively greater danger to the patient from his own sputum as compared to the danger from bacilli coming from without must be quite evident. In suitable cases of pulmonary tuberculosis artificial pneumothorax should be induced, to make the sputum free from tubercle bacilli. Constipation should be avoided and any catarrhal condition of the bowel should be immediately treated. Patients suffering from deficiency of hydrochloric acid in the stomach should be given this acid regularly as it has been found that in such cases the ulceration takes place higher up in the bowel. The general resistance of the patient to infection should be built up by suitable diet and particularly by a proper supply of necessary vitamins. The importance of cod-liver oil and tomato juice in the prevention of the disease has already been mentioned. Here is some work

for the King George Thanksgiving (Anti-tuberculosis) Fund to do. While educating the public against the bad habit of spitting in public places, it must also point out the danger from swallowing the infected sputum. The degree of danger to the intestine to which the patient suffering from open pulmonary tuberculosis is constantly exposed as compared to others, is not generally appreciated and must be brought home to the public by the Fund. It is believed that tubercle bacilli are more easily absorbed through the intestinal mucous membrane when ulceration is present in it. In such cases, reinfection of the lung through the blood may take place. The marked improvement, noticed in the lungs of some patients who are recovering from intestinal tuberculosis, lends support to the view that ulceration of the intestine is a frequent cause of reinfection of other parts of the body including the lungs. Hence the additional danger of what may be called 'entero-phthisis'.

CORRIGENDUM

We regret that a serious misprint was overlooked in Captain A. T. Andreasen's paper on 'The Etherington-Wilson Technique of Intrathecal Nerve-Root Block' which appeared in our December issue, on p. 683, second column, second line, under the heading *Practical details*, the figures '1:500 solution' should read '1:1500 solution'.

We suggest that subscribers make this correction in their December number immediately to obviate a mistake in dosage being made by themselves or others at some future date.

In Memoriam

SINCE our last number was issued His Majesty King George the Fifth of England, Emperor of India, has died.

Most of us must feel that in losing our King-Emperor we have sustained a personal loss. In the history of the world there has been no sovereign so well known and so well loved by his many millions of loyal subjects.

To the medical profession in particular King George had endeared himself. Seven years ago, during his serious illness, for King George as a patient, we all experienced that special feeling of sympathy that a doctor has for any sufferer and although we felt a little justifiable pride that members of our profession had steered him safely through the grave dangers of pneumonia in a man of his age, yet no one realized better than we how much depends on the courage and will-power of the patient himself on such an occasion.

King George always took the greatest interest in all medical institutions and activities, and his recent great benefactions are characteristic of his attitude towards the sick and indigent among his subjects. When large sums of money were collected in this country, first as a thanksgiving for the King's recovery from his illness and again later to commemorate his twenty-five years' reign, instead of allowing this money to be used for erecting some majestic memorial in cold marble which might have stood as a monument to his greatness for a thousand years, he was content to build a memorial in his subjects' hearts by directing that this money should be devoted to the sick of the present generation.

We have lost a great King, a very sincere friend and a great patron of our art to whose memory we shall always pay tribute.

Indian Medical Gazette

FEBRUARY

JHIN-JHINIA, OR NEUROMIMESIS?

CHRISTMAS of 1935 has brought to medical practice in Calcutta the enlivening stimulus of a new 'disease' to ruffle the even tenor of our existence in a land where the routine of malaria, cholera, dysentery and kala-azar is seldom disturbed by anything more exciting than an outbreak of epidemic dropsy or cerebro-spinal meningitis. Though we shall allow them to remain, lest their absence lead to a misinterpretation of our attitude towards this new 'disease' we find, on referring to the *Shorter Oxford English Dictionary*, that the inverted commas we have used are unnecessary; the first meaning of the word *disease* is 'absence of ease, uneasiness; inconvenience, annoyance; disturbance; trouble—1623; a cause of discomfort—1712; molestation—1493'. A more accurate description of the *jhin-jhinia* epidemic that is raging in this part of Bengal could scarcely be given.

The 'disease' appears to have broken out first in September in a village some 50 miles from Calcutta, and though it became a popular local tradition, it does not seem to have attracted much medical attention until the middle of November.

At this point the provincial health authorities were informed of its existence and proceeded to investigate it. At the same time the attention of the daily press was attracted and fantastic stories regarding the disease were published in some of the newspapers, both vernacular and English, in the province. Coincidentally with wider publicity, the 'disease', which had hitherto only spread slowly from village to village, acquired powers of more rapid dissemination. We were warned by frequent alarming reports that the disease was rapidly approaching Calcutta and in due course it arrived—just about Christmas time.

For those who are not familiar with the 'disease', we should perhaps at this point describe some of the symptoms. There was one symptom that was absolutely constant; that was a tingling sensation of the sole of the foot or feet, usually of the big toe. The 'disease' derived its name from this symptom (the Bengali *jhin-jhin* means tingling), and without it no combination of symptoms was *jhin-jhinia*! Another symptom was a feeling of pressure in the head with or without actual headache, and the third pathognomonic sign

which completed the syndrome was violent trembling of the whole body. The last sign, though one of frequent occurrence, was usually delayed until 'treatment' was undertaken—but as everybody knew what treatment was indicated, namely, continuous drenching with cold water, it was seldom that the symptom-complex was allowed to fall short of its full development!

The understanding of the physiology of the disease required a knowledge of Newton's laws of gravity, but little else. According to the local tradition, the 'disease' was caused by a perverse tendency—not fully explained—of the blood to run away from the feet and into the head, hence the tingling due to ischaemia of the toes and the sense of pressure and headache due to congestion.

The rationale of the treatment was even more direct; in order to reverse the flow, the patient was tied to a post to prevent him, or more often her, from lying down—an action that would lead to disastrous consequences—and cold water poured over the head. A not uncommon complication, or sequela, and one that proved fatal in a few cases, was pneumonia; and this complication occurred in those that had received the most thorough and prolonged 'treatment'—an indication of the malignancy of the disease, it is claimed!

The epidemiology of the 'disease' is interesting; it is apparently extremely contagious! The incidence of one case in a village is rapidly followed, often within the hour, by other cases, and the arrival from an 'infected' village of a clerk at a jute mill led to the occurrence of 28 cases on the following day. Another peculiarity of the disease is that the attack usually comes on when the patient is in a crowded place, seldom when he is in his own home, and in Calcutta the highest incidence occurred in the markets whilst the patient was quietly listening to stories of other people who had been similarly attacked.

Most of the victims knew immediately when they were attacked as they had either seen other instances of the disease or the symptoms had been described to them by friends or relatives who had been in contact with the 'infection'; this provides strong presumptive evidence that carriers play a part in disseminating the virus. Deaths have of course been reported; these have apparently been due rather to the complication than to the disease itself; the actual causes of death in these instances have been varied, cerebro-spinal meningitis, apoplexy, fractured skull, and pneumonia following prolonged immersion being amongst those reported.

Encephalitis lethargica, chorio-meningitis, meningitis aseptica and even Landry's paralysis

have been suggested as the diagnosis of this epidemic disease. The fact that most of the cases have been mild and that few deaths have been reported must not, we have been told, make us take the matter lightly, as even the most serious diseases exhibit mild manifestations in some people, and the exponents of the neo-Sydenham school of epidemiological thought warn us that these may only be the 'aura' of a much more serious epidemic.

A number of cases of *jhin-jhinia* have been admitted to the larger hospitals in Calcutta and investigations have been carried out. Those that were not suffering from some definite organic disease showed no symptoms, either subjective or objective, when they had once recovered from the drastic treatment that they had received outside; nevertheless, they were in many instances submitted to a very thorough examination; unimportant abnormalities, such as a high eosinophil count, which could be accounted for by a hookworm infection, and exaggerated knee jerks were found in some of them, and, in about half the cases in which lumbar puncture was done, the spinal fluid came out under slightly increased pressure; otherwise clinical, bacteriological and biological tests showed no pathological deviations from the normal.

After studying this 'disease' from an epidemiological and a clinical point of view it is very hard to escape the conclusion that in the vast majority of cases the diagnosis is neuromimesis or, in the words of the dictionary, 'the hysterical simulation of organic disease'. To be able to say that the whole *jhin-jhinia* epidemic was the result of mass suggestion amongst an ill-educated population would necessitate an omniscience to which no one can lay claim, as it is possible that there is underlying this hysterical display an epidemic of mild but unusual nature in which the transient nervous manifestations are prominent symptoms. Any real evidence for the existence of such an epidemic is, however, lacking. The symptoms that have been described are unlike those of any recognized disease and do not constitute a symptom-complex that could be fitted to an infection or lesion of any particular part of the nervous or any other system. The frequency with which certain subjective symptoms occur has been cited as evidence of a common pathology and of the epidemic prevalence of some infection, but, as an officer in charge of one of the larger Calcutta hospitals pointed out, the constancy of the initial symptoms is one of the strongest pieces of evidence in favour of the hysterical nature of this syndrome, as such a degree of constancy is unknown in the onset of any organic disease. However, it is still necessary to keep an open mind and to investigate any cases in which the symptoms are more definite and less transitory.

The panic that was created was very considerable, and, though the incident has had its comic side, it has also had its serious one. Fear alone is a predisposing cause of disease, and the severe treatment that was administered was in many cases a determining one. The legitimate work of the hospitals in Calcutta was interrupted by the steady flow of *jhin-jhinia* cases, all of which required individual attention as there was always the risk that some real organic condition might be masked by the hysterical manifestations, and the city ambulances were kept busy day and night. The opportunists have not been slow to improve the occasion; *jhin-jhinia* cures and prophylactics are advertized freely, and healers of the cure-guaranteed school have been busy, and have no doubt done a great deal of good in their own way.

Fortunately, the Government took a wise step at an early date; the Hon'ble Minister, Sir Bijoy Prasad Roy Singh, called a conference of representatives from the leading hospitals and issued a communiqué which has done much to quell the panic.

The whole incident does not reflect very great credit on the local medical practitioners and the local health authorities where the 'epidemic' started. They seem to have accepted hearsay reports too readily, instead of doing a little personal investigation, to have looked up in textbooks and journals details of obscure nervous diseases, instead of applying a little common sense, and to have been too keen to display their erudition by writing reports, issuing warnings through the press, and suggesting elaborate procedures for treatment, instead of attempting to allay the panic by pointing out that the attack, whatever it was, was of short duration and of a quite harmless nature. To certain sections of the press also must be attached some of the responsibility for the panic (and we have little doubt that they will attempt to justify their scare-mongering by maintaining the tradition), as they published very misleading details, issued unnecessary and ridiculous warnings, and made the topic one for daily double-column headings.

Returning to our original contention, we feel that we have justified the use of the word *disease* on many counts, but to justify 'molestation—1493' it will be necessary to recount an incident that happened at the height of the 'epidemic'. A citizen was peacefully walking along one of the main streets in Calcutta when he was suddenly accosted by four men who accused him of having *jhin-jhinia* and, despite his protests, rushed him to a water tap near by, poured buckets of water on him, and then decamped; when their victim had recovered he found that his wallet which had contained a hundred rupees was missing!

Medical News

THE SOCIETY OF BIOLOGICAL CHEMISTS, INDIA

BIOCHEMICAL AND ALLIED RESEARCH IN INDIA IN 1934

THIS publication which has just come out covers a little over a hundred pages. It is an annual publication that attempts to summarize the various research work carried out in India on biochemical and allied problems. The subjects discussed come under the following headings:—enzymes, agricultural chemistry, foods and nutrition of farm animals, dairy chemistry, vegetable physiology, phytopathology, progress of research on nutrition in India including work on vitamins, biological chemistry in relation to pathology, pharmacology and therapeutics, and chemistry of sanitation. As in other annual reports of a similar nature, the different sections have been summarized by different contributors. A few duplications may be observed here and there but they can be avoided by a careful scrutiny of the summaries received from the contributors by the committee of publication. A few other shortcomings, such as the omission of a subject index, the choice of the subject headings, the prominence given to the names of the authors, the want of proper sequence of subjects under each heading, etc., will, it is to be hoped, disappear in future.

An interesting feature of the publication is the attention given to medical and agricultural problems, subjects which are of vital importance to India. For a vast country like that of India, with ever-increasing centres for research work, a publication like this should be welcome to everyone. It will not only co-ordinate the different types of work carried out in this country, but will act as an incentive to the workers in different centres. For a scientist, busy with his extremely specialized work, with little time to go through the growing mass of publications, even within India, it should prove to be a welcome addition and help him to keep in touch with the recent developments of a new but rapidly-growing science, the science of biochemistry.

S. G.

BERRY-WHITE MEMORIAL

THE following speech was delivered by Dr. B. Dey, L.M.P., on the 26th October, 1935, when the Students' Union of the Berry-White Medical School celebrated Founder's Day:—

'Mr. President and Gentlemen,

We have met here to-day under the auspices of the Re-Union and Founder's Day Committee to deliberate upon the ways and means of serving humanity as best we can.

As a member of the Re-Union I venture to take the liberty of diverting your attention to a matter which is of no less importance.

It has become customary with us to observe the Hospital Day and the Founder's Day, when a meeting is convened, lectures delivered, a procession through the town of Dibrugarh organized, and money collected for the Hospital Fund.

Many people are quite ignorant of the significance of the Founder's Day. Who the founder was, and what was the extent of his sacrifice for this noble institution, the Berry-White School of Medicine? 16th November, 1896, may well be called a red-letter day in the annals of the medical education of the Assam Province.

It was on this day that Brigade Surgeon John Berry-White, of revered memory, bequeathed to the Charitable Hospital, Dibrugarh, the sum of Rs. 50,000 to be applied towards founding the medical school in Dibrugarh for the instruction of youths who are natives

of India and one of whose parents, at least, is a native of or has for the space of 10 years been resident in the province of Assam.

The Dibrugarh Medical School, and for the matter of that the majority of the members of our service in the province, owes its existence to the magnanimity of this large-hearted and philanthropic Brigade Surgeon.

Mere naming of the medical school after him or observing the Founder's Day in my opinion is not a suitable recognition of greatness of the departed soul, but we must do something more to keep his memory ever green in our mind.

Besides observing Founder's Day, I propose that a memorial fund in the name of the founder may be started, and all the students and ex-students of this school may be appealed to contribute their mite. It may continue till the fund is sufficiently developed when it may be utilized in procuring a statue, or a bust, or a life-sized oil painting of the founder, as the fund permits, to be placed in the medical school, with a brief history of the fund inscribed in a marble tablet. This will be a source of inspiration to anybody who might come across the statue and know more about the man.

We would be failing in our duty if we do not worship the heart that was so great and imbibe the spirit of his soul.

By honouring the great, we also will feel ourselves highly honoured.

With these few words, I again appeal to my fellow brothers to give their serious thought to my humble suggestion and come to a favourable decision.

We understand that the suggestion was readily accepted and Rs. 300 immediately subscribed to create the memorial fund.

It is hoped that all ex-students and others will subscribe to the fund. Money collected will be deposited in the savings' bank at the Dibrugarh post office. A committee has been formed and all information will be supplied on request by the President, Students' Union, Berry-White Medical School, Dibrugarh, Assam.

WORKMEN'S COMPENSATION PAMPHLET

WE have received a copy of the fourth and revised edition of a special pamphlet entitled **WORKMEN'S COMPENSATION IN INDIA** containing 'NOTES FOR THE INFORMATION AND GUIDANCE OF EMPLOYERS AND INSURANCE AGENTS', recently published by the Calcutta Claims Bureau, 26, Dalhousie Square, Calcutta. This pamphlet, which is similar in design to the previous editions, now contains further details and comments regarding the Workmen's Compensation Amendment Act which came into full force in British India, with effect from 1st July, 1934.

The following, among other items, are dealt with:—scope and persons protected; employees included within the definition of 'workman'; civil suits for damages; what is accident; compensation for disease; what accidents are included; amounts of compensation payable for death, permanent disablement and temporary disablement; the 'waiting period'; notice of accidents; reports of fatal accidents; liability for contractors' employees; penalties; administration by commissioners; insurance facilities; cover provided; and procedure in handling claims under the Act.

Written in simple language free from technicalities, the pamphlet should prove of great interest and assistance to all employers who may be called upon to pay compensation and also to legal practitioners and injured workmen themselves who may have recourse to the provisions of the Act.

Workmen's Compensation has already assumed considerable importance in this country, since the first introduction of the Act in the year 1924, and now concerns employers and employees in practically all forms of organized industry. Following the recommendations of the Royal Commission on Labour, the original Act

was materially amended in the year 1934 when numerous additional classes of employees were brought within its scope and the scales of compensation were increased, the increases in the cases of the highest and lowest paid employees being in the vicinity of 100 per cent. The 'waiting period' during which no compensation is payable was reduced, penalties were introduced for the first time, for failure, on the part of the employer, to submit certain reports and returns as required, and there was a general 'tightening up' of all the provisions in the Act in order to avoid evasion of liability.

Many employers will desire to know exactly their legal position in cases of injuries or deaths caused by earthquakes and other similar catastrophes of nature, deaths and injuries caused by attacks of wild animals, including snakes, death due to heart failure following the strain of ordinary work and also their liability in cases of certain diseases, such as those specified as 'occupational diseases', or where diseases, such as pneumonia and tuberculosis, are contracted in accidental circumstances.

The pamphlet deals with these various points in simple language and in the manner which can readily be understood by a layman.

The scheme adopted by insurance companies in connection with the grant of indemnity to cover employers' liability to pay compensation under the terms of the Act is also fully dealt with, samples of the proposal and policy forms being included. The Calcutta Claims Bureau, which was organized when the present Act was introduced in the year 1924 by practically all the leading insurance companies operating in India, acts on their behalf in the settlement of the claims arising under the policies issued by those companies.

The details contained in the pamphlet may, therefore, be regarded as authoritative and based upon the experience gained in the handling of a very large volume of claims since the Act was first introduced. Copies of the pamphlet may be obtained, at a nominal cost, on application from any of the leading insurance companies operating in the Calcutta area.

THE PARKES MEMORIAL PRIZE, 1935

SURGEON-LIEUTENANT J. L. S. COULTER, Royal Navy, has been awarded the Parkes Memorial Prize for the year 1935, a gold medal and a sum of £30, for his essay on 'Tropical Service in the Royal Navy'.

The Parkes Memorial Prize is awarded annually to the writer of the best essay on a subject connected with Naval or Military Hygiene.

The competition is open to medical officers of the Royal Navy, Army, and Indian Army, with the exception of the professors and assistant professors of the Royal Naval Medical School, Greenwich, and of the Royal Army Medical College, London, during their term of office.

THE INDIAN HONOURS LIST

1ST JANUARY, 1936

THE following are the names of medical workers in the Indian Honours List of date 1st January, 1936. We offer them our congratulations:

Knighthood

Colonel C. I. Brierley, lately Inspector-General of Civil Hospitals and Jails, N.-W. F. P.

M. V. Mehta, Medical Practitioner, Bombay.

C.I.E.

Lieutenant-Colonel W. Ross Stewart, Surgeon to Viceroy; Major R. S. Aspinall, Civil Surgeon, Ajmere Merwara; Dr. James Cairns, Chief Medical and Health Officer, N. W. R.

C.B.E.

Lieutenant-Colonel A. M. Dick, Professor of Ophthalmology, King Edward Medical College, Lahore.

M.B.E.

K. S. Sethna, Health Officer, Delhi Municipality.

Kaiser-i-Hind Medal

First Class

R. N. Parmanand, Chief Medical Officer, Adams Wylie Memorial Hospital, Bombay.

Kaiser-i-Hind Medal

Second Class

Miss H. M. Lazarus, Principal, Lady Willingdon Medical School, Madras; Miss C. J. Oliver, Nursing Sister, Lady Minto's Indian Nursing Association, New Delhi; Mrs. E. Sims, Matron, British Families Hospital, Mingaladon, Burma; Mrs. L. Tarleton, Superintendent, Jaswant Female Hospital, Jodhpur; Miss Alice Wilkinson, Nursing Superintendent, St. Stephen's Hospital, Delhi; Girdharilal Batra, Assistant Director of Public Health, Bengal; N. A. Pitale, in charge of Naini Leper Asylum Laboratory, Allahabad.

Kaiser-i-Hind Medal

Third Class

Mrs. C. E. M. Gillespie, Matron, Victoria Hospital, Jubbulpore; George Henderson, Medical Missionary, Sankeshwar, Belgaum; J. D. Gupta, Sub-Assistant Surgeon, Sadar Hospital, Jessore; S. K. Galvankar, Medical Practitioner, Bassein, Bombay; S. R. Jawadekar, Private Medical Practitioner, Jamner, East Khandesh, Bombay.

Sardar Bahadur

Sardar Sahib Sardar Lehna Singh, Sub-Assistant Surgeon, Abohar, Ferozepore District; Sardar Ragbir Singh Dugal, Private Medical Practitioner and Managing Director, Sports Syndicate Limited and Councillor, Municipal Corporation, Rangoon; Rai Sahib Subedar Mula Singh, I.O.M., First Assistant to Director, Nutritional Research, Indian Research Fund Association, Coonoor.

Rai Bahadur

Rai Sahib Kumar Nath Bagchi, Chemical Analyst to Government of Bihar and Orissa, Public Health Department, Patna; Babu Baikuntha Kumar Nandy, Habiganj, Sylhet, Assam; Hukum Chand Gupta, Civil Surgeon and Superintendent of Jail, Kohat.

Rao Bahadur

Dr. Ramchandra Venkatesh Mone, Civil Surgeon, Bijapore, Bombay Presidency.

Rai Sahib

Babu Mahesh Prasad Mehra, Medical Officer, Khairabad Dispensary, District Sitapur; Lala Bansi Lal, Sub-Assistant Surgeon (retired), Lahore, Punjab; Pandit Vindeshwari Prasad Dikshit, Assistant Surgeon in charge of Victoria Hospital, Rewa, Central India.

Rao Sahib

Tattai Narasimha Srinivasan Raghava Acharya, Senior Public Health Assistant, King Institute, Guindy, Madras; Rao Rama Rao, Senior Surgeon, Civil Hospital and

HONOURS GIVEN FOR WORK IN CONNECTION WITH THE QUETTA EARTHQUAKE

His Excellency the Grand Master of the Most Eminent Order of the Indian Empire is pleased to announce that His Imperial Majesty The King, Emperor of India, has been graciously pleased to make

the following appointment to the said Order, for services rendered in connection with the Earthquake in Baluchistan, 1935:—

ORDER OF THE INDIAN EMPIRE

To be a Companion

Lieutenant-Colonel Samuel George Steele Haughton, O.R.E., Indian Medical Service, Officiating Assistant Director of Medical Services, Zhob (Independent) Brigade Areas, Western Command.

ORDER OF THE BRITISH EMPIRE

His Imperial Majesty The King, Emperor of India, has been graciously pleased to give orders for the following appointments to the Most Excellent Order of the British Empire, for services rendered in connection with the Earthquake in Baluchistan, 1935:—

To be Officers

Lieutenant-Colonel Vaman Raghunath Mirajkar, Indian Medical Service, Professor of Operative Surgery, King Edward Medical College, Lahore, Punjab.

Lieutenant-Colonel Jacob William Vanreenen, Indian Medical Service, Officer Commanding, No. 4 Indian Hospital Corps, Quetta.

Kaisar-i-Hind Medal

His Excellency the Viceroy and Governor-General is pleased to announce that His Imperial Majesty The King, Emperor of India, has been graciously pleased to award the Kaisar-i-Hind Medal of the First Class for Public Service in India, for services rendered in connection with the Earthquake in Baluchistan, 1935, to:—

Major James Ernest Gray, Indian Medical Service, Civil Surgeon, Karachi, Bombay.

Captain Bertrand Temple-Raston, Indian Medical Service, Civil Surgeon, Dera Ghazi Khan, Punjab.

INDIAN MEDICAL COUNCIL

BREVET-COLONEL H. H. THORBURN, C.I.E., M.B., CH.B., I.M.S., Officiating Inspector-General, Civil Hospitals and Prisons, N.-W. F. P., has been nominated by the Government of the N.-W. F. P., under clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Dr. Saranjan Khan, resigned.

Current Topics

A New Operation for Hæmorrhoids

By M. SAMY

(From the *Medical Press and Circular*, Vol. CXCI, 21st August, 1935, p. 156)

HÆMORRHOIDS or piles are very common in Egypt, and present all the usual characteristics and complications. People from the Egyptian villages and small towns usually seek the advice of the doctor when it is very necessary to operate on account of repeated hæmorrhages, inflammation, thrombosis or the enormous size of the piles. Before commencing to describe the new operation it is better to mention some few hints about the surgical anatomy of the rectum and anal canal, as this facilitates the understanding of the operation.

Surgical anatomy.—From a surgical standpoint the rectum extends from the pelvi-rectal junction, situated in front of the sacral promontory, to the exit of the anal canal on the surface, between the nates. Its length is about six to eight inches. From the anatomical and developmental point of view this length of the intestinal canal is divided into two separate parts:

(a) *The rectum proper*, which is developed from the hind end of the hindgut and is endo-dermal in origin. It extends from the pelvi-rectal junction to the upper end of the narrow anal canal. The rectum is five to six inches long, and is lined with thick columnar epithelium containing numerous tubular mucous glands. Its mucous membrane is thrown into transverse folds. Usually three of these folds are specially prominent, one on the right and two on the left at a lower and higher level. These form the valves of Houston, and may interfere with the passage of the protoscope.

(b) *The anal canal*, which is developed from the epidermal invagination of the cloaca (proctodæum), and is originally separated from the rectum by a membrane. This membrane disappears about the fourth month of the intra-uterine life. The thin white line of Hilton which is seen in the adult at the ano-rectal junction is the remains of the edges of this membrane. The anal canal is smooth and lined with stratified columnar epithelium. The skin around the anus is thrown up into radiating rugæ.

There is a series of longitudinal processes at the upper end of the anal canal. These are called the

columns of Morgagni. Between these columns we find the pit-like sinuses which are called the valves of Morgagni. These latter may be torn away or lodge foreign bodies, and serve as a starting point for perianal infection.

The peritoneum extends to within 2½ to 3 inches from the anus on the anterior aspect of the bowel. Posteriorly it does not reach lower than about five inches from this point. The muscular wall of the rectum and anus consists of longitudinal and circular fibres homogeneously distributed and fusing just above the ano-rectal junction with the levatores ani and internal sphincter muscles. These, together with the thick ring-like external sphincter ani surrounding the anal canal, establish a certain amount of voluntary control over the evacuation of the lower bowel. The external sphincter and levatores ani are supplied by the pudic nerves, while all the other muscles get their nerve supply from the sympathetic.

The superior hæmorrhoidal artery, a direct downward continuation of the inferior mesenteric artery, supplies the upper part of the rectum and rectal mucosa. The inferior hæmorrhoidal branch of the internal iliac artery supplies the anal canal, lower part of the rectum and ischio-rectal fossæ. Around and in the wall of the lower part of the rectum, free anastomoses occur between the superior and inferior hæmorrhoidal arteries, and to a lesser extent with the middle hæmorrhoidal arteries, which, however, are mainly exhausted in supplying the peri-rectal cellular tissue.

The venous return has a special surgical importance. The superior hæmorrhoidal vein returns the blood from the rectal wall and mucosa, and passes into the valveless portal circulation. The inferior hæmorrhoidal veins drain the anal canal and pass across the ischio-rectal fossæ to the systemic circulation. The tributaries and radicles of these veins inosculate and anastomose freely in the submucous tissue of the lower end of the rectum. The hæmorrhoidal plexus surrounds the rectum and communicates in front with the vesical plexus in the male and the utero vaginal plexus in the female. It consists of two parts, an internal in the submucosa and an external outside muscular coat of the rectum. The internal plexus presents a series of dilated pouches which are arranged in a circle around the gut just above the anus. These pouches are connected by transverse branches and drain mainly into the superior hæmorrhoidal vein.

The inferior hæmorrhoidal vein drains the lower part of the external plexus into the internal pudendal vein, and the middle hæmorrhoidal veins drain the middle part into the hypogastric veins. The upper part is drained by the superior hæmorrhoidal vein which forms the commencement of the inferior mesenteric vein, a tributary of the splenic vein. A free communication occurs between the portal and systemic venous system through the hæmorrhoidal plexus.

So it is evident that any obstruction to the venous outflow of the portal or systemic circulations is reflected to the dependent area in the submucosa of the lower end of the rectum, where the distended veins bulging into the rectal lumen constitute hæmorrhoids or piles. The mucosa covering this area is surgically called the pile-bearing area.

The variety of operations used at present for the radical cure of hæmorrhoids denote that the present operative treatment is incompletely satisfactory up till now. The advantages and disadvantages of these operations are well known. Theoretically, the operations which remove the whole pile-bearing area of the mucous membrane seem to be the best. It is specially useful in old-standing cases of piles with much prolapse and enough laxity of the mucous membrane to ensure that no tension exists on the stitches uniting the skin and the mucosa.

The operations, removing the have been used up till now have some of these disadvantages are: (1) Stricture formation; (2) danger of rectal insecurity; (3) the operation takes a long time; (4) much bleeding occurs during the operation; (5) the wound takes a long time to heal.

The writer has devised an operation which removes the area of the mucosa of the rectum bearing the diseased piles with a little of the normal mucosa above it. The amount of normal mucosa removed depends upon the age of the patient, as will be described below. The above disadvantages are got rid of in this operation. Its additional advantages over modern operations will be mentioned below. I shall now mention a few hints about this operation.

(1) INDICATIONS

This operation is indicated in every case of internal or combined internal and external piles. It is especially indicated in piles that are either long-standing or prolapsed, however slightly. It is also indicated in all the cases that belong to the so-called idiopathic category of piles, but it may be justifiably done in cases of severe piles from cirrhosis. In these cases, the patients should be warned that recurrence is inevitable in a few months. The operation might be injudicious and harmful if cancer is present, or if the piles are caused from enlarged prostate, uterine fibroids or cardiac disease.

(2) PREPARATION OF THE PATIENT

First of all the patient should be medically fit for the operation. Any constitutional fault or disease (e.g., syphilis, etc.) which may exist should be corrected. The teeth should be put in good order and cleansed. An essential point in the preparation of patients for rectal operations is the absolute emptiness of the large bowel, so that no soiling of the wound takes place during the operation if the patient coughs or strains from anaesthesia or other causes. Any proctitis, whether catarrhal, purulent, gonorrhoeal, bilharzial, dysenteric, gummatous or tuberculous, yaws and thread-worms of the rectum, should be thoroughly treated. It is better to take the patient to the hospital at least two days before the operation. The bowels should be freely relieved each of the three days before the operation by aperients given every twenty-four hours. One and a half to two ounces of castor oil may be given every night for this purpose. Any other good and desirable aperient which the patient likes may be advantageously used.

Day before the operation.—If the castor oil or aperient, taken at night, did not act satisfactorily a dose of saline purgative (e.g., magnesium sulphate, magnesia, or sodium sulphate) should be taken early in the morning.

Food.—8 a.m. breakfast, one small piece of bread, butter, jam or honey. 11 a.m., lunch, a cup of milk. 6 p.m., dinner, a cup of soup.

Evening before the operation.—A high soap-and-water enema is made with the aid of a long catheter. This enema is repeated if necessary until it comes back clear. Then the following draught is taken:

R Tincture opium	℥ x
Solution of ammonium acetate	℥ xxx
Spirit of chloroform	℥ xv
Tincture of catechu	℥ ½
Compound tincture of cardamom	℥ ½
Cinnamon water	℥ i

This opium draught is useful in many ways. It induces a good sleep at night and prevents soiling of the area of the operation by inhibiting peristalsis. So when the enema of the next morning is given the lower bowels are emptied without causing peristalsis or bringing fresh material from above into the field of the operation. The next step is to shave the area of the operation and a sufficient area surrounding it. It is better to use a good quality powder (sulphide) for the removal of the hair, to avoid scratches and superficial wounds made by the razor in shaving. The amount of the powder used should be just sufficient to remove the hair, because much powder also dissolves some of the horny layers of the skin. Shaving or the use of a reasonable amount of hair-removing powder is efficient in removing the sodden epithelium and its contained bacteria.

The patient should then take a good hot bath and should thoroughly cleanse the skin of his body, especially the skin of the perineum.

Morning of the operation.—Four hours before the operation a plain tepid water enema (1½ pints) is made. This is repeated if not returned clear. After that the patient is instructed to void urine and also to get the bowels fully relieved. Now the anus, anal canal and lower part of the rectum are washed out with 2½ per cent carbolic acid solution by means of a two-way tube. The skin from the waist to the middle of the thighs is now prepared in the same way as for the cleanest laparotomy.

It is prepared in the following order: (1) Wash the parts with soap for five minutes. No undue scrubbing or rubbing should be done, because they may wake up into activity germs lying dormant in the deeper parts of the skin. (2) Cleanse with ether by firmly rubbing the skin with a swab soaked in ether. This dissolves and removes fat and sebaceous matter and sterilizes the layers of the skin to a great depth. (3) Cleanse with 0.2 per cent biniodide of mercury in alcohol. This solution is a very powerful germicide, efficient antiseptic, and does not react much with albumin. (4) Paint the parts with 1/1,000 aqueous solution of biniodide, which is more efficient in penetrating the tissues than the alcoholic solution. The formula of this solution is as follows:

R Biniodide of mercury	1.0
Potassium iodide	1.0
Sterilized water	1,000.0

(5) Thoroughly cleanse with pure benzene. (6) Paint with ether again. (7) Leave place to dry and then paint twice with 2.5 per cent iodine in 70 per cent rectified spirit. The place should be dry before painting; because alcoholic antiseptic solution acts properly when applied to a dry surface, as moisture causes the cells of the prickly-celled layer of the skin to swell and hinders the action. The iodine tincture, in addition to its sterilizing properties, stains the skin, rendering apparent at once any unsterilized area exposed, should the towels require rearrangement. (8) The anus, anal

canal and lower part of the rectum are painted with 2.5 per cent iodine tincture by means of sponges and sponge forceps. (9) The perineum is then rubbed with 70 per cent alcohol for five minutes. (10) The area is then covered with a sterilized towel. (11) A hot water bag is placed over the towel for the fifteen minutes just before the operation.

Forty-five minutes before the operation 0.01 of a gramme morphine hydrochloride, 1/200 of a grain hyoscine (scopolamine) hydrochloride and one ampoule of coaguline ciba are injected separately under the skin. The morphia corroborates the action of the previous dose of opium in inhibiting peristalsis. Also, together with the hyoscine hydrochloride, it produces a kind of twilight sleep and helps the anaesthesia much. The coaguline increases the coagulability of the blood and thus lessens bleeding during the operation. The patient usually sleeps after the operation, and this is very useful in every way. The patient awakes from his sleep after the pain of the operation (if any exists) is completely or mostly gone.

The above method of preparation is most suitable and ideal, but minor modifications may be made in it to suit hospital cases, children, old people, and people with special constitutional diseases.

(3) ANAESTHESIA

The patient should be placed comfortably upon the operating table and the operation should be completed as much as possible without his knowledge. He should be made to believe that he is still being prepared. The proper anaesthetic suitable for each case should be chosen by the anaesthetist. Most of my cases did very well with sacral, regional and local anaesthesia. If general anaesthesia is given the patient should be warmly wrapped with blankets and anaesthetized outside the actual operating theatre. In the theatre the blankets are removed and substituted with warm bath towelling to maintain the body warmth. The writer employs the following method of anaesthesia with very satisfactory results:

The instruments used are: (1) A syringe, 20 c.c. capacity, with a glass or metal plunger. The barrel must be fitted with rings or some other form of finger grip to enable the operator to get sufficient and steady pressure on the plunger. (2) A syringe, 10 c.c. capacity, and of the same kind as the above one. (3) Six hypodermic needles. These should be fine, sharp, smooth, bevelled and accurately fitting to the syringe, so that the joint is absolutely air-tight; two of the needles should be about 7 cm. long, two of usual length, 4 cm., and the remaining two each 15 cm. long. The syringe and needles should be sterilized in plain water, which should not contain any trace of sodium carbonate or bicarbonate, because these salts decompose the novocaine solutions which are used in this method.

Some 2 per cent solution is put in a glass flask with a cotton-wool cork and sterilized for fifteen minutes. Then 1.5 c.c., or 25 drops, of sterilized adrenaline hydrochloride, 1/1,000 solution, is aseptically added to it just before use. The adrenaline constricts the blood vessels, and this lessens the absorption of novocaine, localizes its action, prolongs its period of activity and minimizes bleeding during operation.

Anaesthesia.—The patient is placed in the left semi-prone position with the knees well drawn up. The sacral hiatus is felt just above the sacro-coccygeal joint. Two little spinous processes guide its entrance, and the opening is just below and between them. The skin at this spot is anaesthetized by a small hypodermic needle and an ordinary syringe containing $\frac{1}{2}$ c.c. of the 2 per cent solution of novocaine mentioned above. Now a 7 c.c. needle is pushed gently through the hiatus, and will be felt to puncture the membrane. Then the butt of the needle is pushed downwards towards the perineum and the needle passed backwards almost parallel with the posterior surface of the sacrum. It should pass a distance of 1½ to 2 inches. If cerebro-spinal fluid flows out the needle should be withdrawn. If blood

comes out of the needle (due to vein puncture, etc.), the position of the needle is changed until no blood comes out of it. Then 20 c.c. of the above 2 per cent solution of novocaine is injected. The syringe and needle are then withdrawn and a small piece of dressing soaked with collodion is placed over the site of the prick of the needle. Then the following solution is prepared and sterilized by the same method as the above 2 per cent novocaine solution, and used after the addition of 1.5 c.c. of sterile 1/1,000 adrenaline hydrochloride solution:

R Novocaine (tablets or powder)	..	1.00
Calcium chloride	..	0.25
Sterilized normal saline solution	..	100.00

15 c.c. of this solution is taken in the syringe.

A medium needle (7 cm. long) is inserted half an inch to one side of the middle line opposite the tip of the coccyx for the depth of about one inch. One and a half c.c. of the solution is then injected. A similar injection is made on the opposite side. Again the medium needle is inserted just to one side of the coccyx and passed up to the hollow of the sacrum, guided by a finger in the rectum. One c.c. is injected in this area around the nerves emerging from the last two sacral foramina. This is done on both sides. One cubic centimetre of the solution is then injected in each ischio-rectal fossa. One c.c. is also injected in each side of the middle line in front of the rectum, and between it and the vagina or prostate, and around the anus. The injection is continued as the needle is advanced.

Now the long needle (15 cm. long), guided by a finger in the rectum, is passed in from a point just outside the anus towards the spine of the ischium. When this latter is felt it is then directed backwards until the outer side of this bone is reached; 2 c.c. are injected at this spot. A similar injection is made on the opposite side. By the above method we safely get excellent anaesthesia of the rectum and perineum after about twenty minutes. After this time the patient's skin should be tested by a pin before beginning the actual operation. This anaesthesia keeps for about an hour.

The patient is placed in the lithotomy position, Clover's crutch being used for this purpose, the buttocks made to project slightly over the end of the operating table and the pelvis is slightly raised. In this position the legs should be near the middle line and the leggings so arranged as to produce no undue opening of the buttocks from each other and thus produce tension on the stitches during the operation. No undue or prolonged pressure should be put on the external popliteal nerves. This is likely to happen in a patient with long thin legs, and may cause temporary paralysis of the peronei muscles. The hands and legs of the patient are gently and securely tied to the operating table. The surgeon sits opposite the perineum and the assistant stands on his right.

The anus and an area one inch in diameter of the skin around it are completely isolated by means of towels and towel clips. The scrotum and penis should be thoroughly retracted above.

Before starting the operation the rectum should be digitally examined to ascertain the position of the piles. The anal canal is then painted with 2.5 per cent tincture of iodine by means of a sponge and forceps, and then the skin of the area around the anus is painted with 5 per cent iodine tincture in 70 per cent alcohol by means of another sponge and forceps. Both forceps are thrown away and should not be used again during the operation.

Now one finger is inserted in the anus and the piles can be coaxed outside. Very rarely this manoeuvre fails to show the piles. If this happens, the anus is very gently dilated to cause temporary paralysis of the sphincters. This is done by putting the index fingers of both hands one after the other through the anal aperture and exerting gentle, continuous and firm traction until the sphincters are felt to relax or give way. When this begins to happen, the pressure from within

is very gradually diminished to avoid overstretching, laceration and tearing of the muscles. It takes about two minutes to produce sufficient dilatation. As full dilatation or stretching of the sphincters and cause much pain after the operation and may produce retention of urine, so it must be avoided as much as possible. The hæmorrhoids now prolapse and come completely into view. With a sponge and forceps the anus, anal canal and rectum are again painted as high as possible with 2.5 per cent tincture of iodine in 70 per cent alcohol. A sterilized bandage 5 cm. in breadth and about 50 cm. long is then used to plug and not to pack the rectum so as to separate it from the field of the operation. The end of this plug is caught by means of a suture of catgut no. 3 about 30 cm. long. The suture is doubled, and its two ends are held by an artery forceps and left to hang down.

Now three lines are chosen in the circle of the anus, in which lines there are very small piles or no piles at all. These lines should be about $\frac{1}{2}$ to $\frac{2}{3}$ of a centimetre in length, and the distances between them should be about equal.

The tissues lying under these lines are left untouched. Tissues, prolapsed piles, mucous membrane and muco-cutaneous junction lying in between the chosen lines are now grasped by three separate pile forceps. Each forceps is made to grasp the whole tissue tightly and firmly. The forceps are applied longitudinally on the bowel, i.e., along the pile, and are left in position as a guide to the site of the pile until the surgeon finds it convenient to deal with them. These forceps hang loose, and are not in the way.

Now one of the forceps, preferably the posterior one, is held in the left hand and drawn anteriorly. If one commences with one of the anterior forceps, the posterior piles may be obscured by the blood, and the smaller piles, which are evident enough before the actual operation is commenced, may be lost sight of after some of the main anterior piles have been dealt with. A very sharp suitable knife is held in the right hand, and a clean cut is made in the skin just lateral (about 1 cm. lateral) to the muco-cutaneous junction, and in the muco-cutaneous junction.

The incision should be lateral to external piles, tags or irregularities of the skin which may exist. By clean dissection the diseased hæmorrhoidal area of the mucous membrane of the grasped portion is separated from the submucous tissue which lies between it and the subjacent muscles. The separation should be as high as possible with thorough undermining of the mucous membrane. The piles and mucous membrane are pulled down below the level of the anus, and then left to rest down without traction. Now the incised skin is thoroughly undermined.

Three or four interrupted twenty-days catgut no. 2 sutures are made between the deeper parts of the undermined skin and the highest line of the undermined mucous membrane above the diseased piles. If the patient is below forty years of age the dissection, undermining and suturing of the mucous membrane should be a little higher than if he is more than forty years old. This is because under the age of forty years some of the piles are immature and hidden, while at the age of forty years or more usually all the piles are mature and apparent. There should be no tension at all on the stitches. These sutures prevent the formation of a hæmatoma and subsequent stretching of the scar. They should take large bites of the deeper tissues, including the deep layers of the skin, sphincter, muscular and submucous walls of the bowel. Now the diseased hæmorrhoidal portion of that part of the mucous membrane is cut away with sharp scissors. This portion never extends beyond two inches from the anus. The cut wants careful judgment, and should be made just below the above sutures. If one leaves too much, the anus becomes surrounded by a crop of outstanding fibrous folds, which may become inflamed and need to be snipped away on a later occasion. Too great a removal may result in inversion of the skin; bleeding points should be immediately held with forceps, and

then underpinned by sutures. The free margin of the skin and cut edge of the mucous membrane are then stitched together by the insertion of a number of interrupted ten-days catgut no. 2 sutures. The sutures should advisably pick up the edge of the sphincter as they are passed. The deep stitches should be done with fine intestinal, round-bodied suture needles, and the superficial stitches with sharp, medium-sized, fully-curved and round-bodied needles. Before closing the wound the tissues should be washed with 2.5 per cent carbolic acid solution and painted with 2.5 per cent iodine tincture. Very great care should be taken to fit and coapt cut margins of the skin and mucous membrane truly and exactly together. The needle is passed through the mucous membrane in such a way as to take up any oozing vessel with it. There should be no eversion of the mucous membrane nor inversion of the skin, nor overlapping nor rolling of the edges of the wound, as these conditions especially the first cause much trouble to the patient afterwards and make him believe that the piles have recurred. Absolute hæmostasis should be ensured. All dead spaces in which blood clots or effusions may collect should be obliterated to avoid septic trouble at a later period.

The sutures should not be tied too tightly otherwise they would strangulate the tissues in their grasp, and by auto-infection of the strangulated tissues, stitch suppuration happens. Very tight stitches may also cut out and produce unnecessary scarring. So each suture should be tied only tight enough to keep the margins of the wound in exact apposition. The sutures should not be directly employed after being taken from spirit, which acts thereby as a caustic. So all suture material should be carefully washed with salt solution before use, if stitch abscess is to be avoided. The same thing is done with the tissues held by the other two forceps or volsellæ, and the plug is then gently and neatly removed.

The area of the operation is thoroughly washed with 2.5 per cent carbolic, painted with 2.5 per cent iodine, and then washed with sterilized saline. Small pieces of glove rubber are put in between the stitches. These allow drainage of any exudate which might happen to form and should be removed after forty-eight hours. A strong stainless safety pin is inserted in the middle of a 20 cm. long drainage tube. The diameter of this tube should be about $\frac{1}{4}$ cm. The tube is wrapped round with gauze, and one end of it is pushed into the anal aperture until the pin comes into contact with the anus. The tube comforts the patient much by allowing the passage of flatus. It also prevents or minimizes bleeding and contamination of the margins of the wound. The pin should be made to touch the anus sagittally and not transversely.

Dressings are applied to the wound, and a thick (1 cm.) ring of sponges is put between the anus and the pin. Thick dressings and cotton are placed over the area of the operation. These dressings should have a hole in their centre to allow the passage of the tube. A bandage with a hole in its middle for the tube is then applied.

All bleeding and oozing should be absolutely stopped before the wound is covered. No skin of the anal margin should be included in any ligature or crushed, otherwise much pain will be induced, and it is possible that a stricture of the anus may afterwards develop. No raw area should be left uncovered by skin, and strict asepsis should be observed. One should take his time in doing this operation accurately, as nothing is gained by undue and showy rapidity. If piles only exist in one or two places in the circle of the anus and the rest of the anus is found to be absolutely free from hæmorrhoids, dissection, undermining, suturing and excision is done in the diseased places only.

AFTER-TREATMENT

The best bed for a patient who has been operated upon by this method is a narrow, fairly high bed, with either a very stiff spring mattress or boards. Another

mattress may be used if necessary. The hygienic condition of the surroundings should be looked after. The legs of the patient should be put together, and he should be moved by the draw sheet and not by holding him, to avoid displacement of the dressing and hurting the patient.

The legs should be kept as near as possible to each other until the wound heals. If the patient has had a general anæsthetic, he should be covered up warmly and conveyed to a warm bed. He should be protected from draughts by covering the head during transit from the theatre to the bedroom to lessen the chances of post-anæsthetic pulmonary troubles.

The after-treatment wants very skilful and conscientious nursing. The air should be allowed to circulate freely in the neighbourhood of the dressing so as to prevent the dressing from becoming moist. The wound should be kept clean and dry the first seven days. Any oozing or discharge should be washed or swabbed off with hydrogen peroxide solution, as it may undergo decomposition and sepsis may result. This hydrogen peroxide solution is somewhat styptic, and cleanses the area by its mechanical action when bubbling off nascent oxygen. The part should be dressed for the first time twenty-four hours after the operation. The wound is gently cleansed with pure ether and painted with 2.5 per cent. iodine in 7 per cent rectified spirit, and a dry dressing applied. After another twenty-four hours the glove rubber pieces are removed and the same cleansing, painting and dressing done. The glove rubber pieces should not be removed before forty-eight hours after the operation, as imperfect drainage leading to tension on the stitches prevent healing by first intention. The wound is dressed in the same way every twenty-four hours until the morning of the eighth day, when the interrupted stitches are removed. By this time the wound would have usually healed aseptically. The time taken by an aseptic wound to heal properly depends upon the age and vigour of the individual and the degree of tension required to close the wound. Discharging wounds may require several dressings in the twenty-four hours. These dressings of the wound should be conducted with the same precautions as to the aseptis of the hands, instruments, etc., as the original operation because many instances of wound infection occur from the after-dressings.

Also it is essential that everything likely to be required should be prepared before the dressings are removed, so that exposure of the wound to air may last as short a time as possible.

If general anæsthesia has been given, no diet should be given to the patient before its direct after-effects have passed away and the patient has become completely conscious. After this the patient is only allowed a pint of plain water in the first sixteen hours after the operation. Coffee and tea are also allowed. If, on the other hand, local anæsthesia has been used, the patient, if he wants to, may begin to drink water directly after the operation but he also is allowed only a pint of plain water, coffee and tea in the first sixteen hours after operation.

If any pain is felt, 10 to 15 grains of meta-aspirin may be given at night. On very rare occasions one is obliged to use trional or even morphia if the pain is severe. Rising temperature and pain suggest suppuration, and usually manifest on the third or fourth day after the operation. This may be delayed as late as the tenth day in case of deep suppuration.

If any retention of urine occurs the patient may be left twelve to fourteen hours without passing a catheter. The conditions being unusual, the patient may be unable to urinate; accordingly it is advisable to allow him to stand by the bed alone in the room. The patient should do no straining, as it does not help him, and only causes pain in the rectum. If retention is still present, a catheter is passed under very strict aseptic conditions. Putting a hot water bag over the hypogastric region directly after the operation is very useful in preventing the occurrence of retention of urine.

The water of the bag should be changed when it loses its heat. One should continue using the hot-water bag until one is sure that the urine is passing normally.

As soon as possible after the operation one drachm of liquor opii sedativus (B. P. C.) should be given. It has enjoyed a reputation for a long time as an anodyne and sedative superior to tincture of opium. Then one ounce of the following mixture is taken every four hours for the first sixteen hours, and every eight hours in the succeeding forty-eight hours, and twice daily (morning and evening) up till the evening of the seventh day after the operation:

R. Liquor ammonium acetate	..	5 $\frac{1}{2}$
Tincture of catechu	..	5 $\frac{1}{2}$
Tincture of opium	..	m x
Compound tincture of cardamoms	..	m x
Distilled water ad	..	℥ 1
Twenty-one doses.		

This keeps the patient constipated until the morning of the eighth day after the operation, when the superficial stitches are removed. The patient, fearing pain, naturally resists any inclination to defæcate, and the desire soon passes away. The tube is removed in the morning of the fifth day after the operation, unless the patient is very uncomfortable from it, or there is much fæces coming down. Under such circumstances the tube is removed earlier than the fifth day, to be reapplied if the patient gets flatulence.

Some twenty-four hours after the operation the patient is allowed drinks, e.g., lemonade, orange water, barley water, caraway water, tea, coffee and beef tea. These drinks are given for seventy-two hours, and no aperient drinks, e.g., tamarindus infusion, etc., should be allowed. Then he is allowed to take bread, butter, jam, boiled potatoes (with some butter, lemon and salt), rice, macaroni, water melon, cooked apples, and similar mild foods in small amounts. Milk should not be given, nor any kind of food which produces much gas (e.g., most of the vegetables), nor foods which have any laxative action. The food should be sufficiently nourishing, but not bulky nor heavy. Variations in quantity and quality of the food should be made according to the patient and the circumstances.

On the morning of the eighth day the patient is given one and a half ounces of castor oil, and after one and a half hours an enema of three to four ounces of olive oil. The patient may defæcate in a bed pan or in a commode by the side of the bed. He should not strain at stool. The bowels are kept open daily, and for a week the stools should be quite fluid. A tablespoonful of petroleum taken twice daily with a mild aperient taken overnight will generally ensure daily a perfect watery action of the bowels. This is essential for a satisfactory cure and the comfort of the patient. The patient may use any good aperient which he likes.

The patient can leave the hospital or nursing home in the afternoon of the eighth day, and should wash the anus and perineum with warm 2.5 per cent carbolic solution after each action of the bowels. He can use senna pods or cascara evacuant, which are excellent aperients. He can eat satisfactory quantities of all kinds of food except the very irritant.

The advantages of this operation over other operations previously used for the radical cure of hæmorrhoids are:

(1) The skin incision includes not only the piles, but also the folds of the skin lateral to them and tags of hypertrophied tissue at the muco-cutaneous junction. In the other operations these folds and tags are not removed, and may require another operation for their removal.

(2) The section of the skin lays open the superficial veins of the inferior hæmorrhoidal plexus, and the œdema which used to happen after some pole operations is either entirely absent or minimized to a great extent.

(3) The hæmorrhoids are not likely to recur when the ligature and excision operation is done properly in

a patient above forty years of age, and the piles present are completely removed. On the other hand, if the patient is under forty years of age at the time of the operation, all the piles may not have developed or matured, so that later in life a second operation may be required for the removal of the piles that have matured. But if the above operation is performed properly in a patient under forty years of age, there is no recurrence.

(4) There is no danger of stricture formation after the above operation, because the three lines of tissues left unincised in the circle of the anus act as elastic bands and prevent stricture formation.

(5) The period of convalescence is very short.

(6) The pain after the operation is either completely absent or minimized to a great extent. This is because of the clean cutting, non-bruising and non-tearing of the tissues during the operation. Also very strict aseptic and antiseptic conditions count much in the prevention of the after-pain of the operation.

(7) Rectal insecurity does not occur because parts of the sensitive mucous membrane which line the anal canal are left unexcised during the operation. The sphincters also are uninjured during the operation. Rectal insecurity usually occurs, at least for some time after operations that totally remove the mucous membrane lining the anal canal.

(8) Primary union usually takes place. The anus, anal canal and rectum are unclean parts of the body, but should not be counted as septic, because they do not contain septic micro-organisms in large quantities. No part of the skin or mucous membrane, as far as we know, is free from pathogenic micro-organisms. Probably the largest number of micro-organisms to a given surface is found in the mouth. The faeces as a matter of fact do not, under ordinary circumstances, contain an exceptional number of pathogenic organisms. With the exception of the *Bacillus coli*, few are pathogenic. So the mucous membrane of the rectum might be favourably compared as regards the number and quality of micro-organisms upon its surface with the skin on the exposed portions of the body, and exceptionally favourable with mucous membrane of the mouth. Accordingly the rectum is not septic, but simply difficult to make clean by the ordinary methods used with other parts of the body.

So, as specified above, it should have specially modified methods in the preparation and after-treatment. When these methods are performed properly we usually get healing by first intention. Healing of the wound commences immediately after the operation and is more rapid the closer the tissues are approximated, as there is less blood clot to be disintegrated and absorbed. Healing of wounds is really a process of inflammation: the blood clot is invaded by capillary loops, which revascularize the area, and then in their turn become obliterated by pressure of the newly-formed fibrous tissue.

Healing is almost identical to resolution. If the tissues are approximated and no injection occurs, healing takes place by first intention, and should be sufficiently progressed in ten days to allow the tissues remaining in apposition without support under normal conditions. A thin layer of blood clot lies between the surface of the wound and penetrates into their irregularities, and the contraction of this clot is at first the chief means of keeping the deeper parts in apposition. There is but a microscopic line of damaged tissue, which together with the blood clot is easily absorbed. A thin layer of granulations develops on either side, and these unite across the wound in a few days, and are transformed into granulation tissue.

Should the tissues not be approximated, or infection occurs, then healing will be by granulation, and takes a much longer time. The larger the wound the longer being the time taken, as the granulations arising from the surface have to grow up and fill the gap. In case of delayed union, ultra-violet rays may be used in order to increase the blood supply to the area of the wound. But the four causes of delayed union (sepsis, syphilis,

foreign bodies and undue movement) are mostly preventable.

Fractures of the Neck of the Femur

By S. A. S. MALKIN, M.B., B.S., F.R.C.S.

(From the *Medical Press and Circular*, Vol. CXCI, 23rd October, 1935, p. 363).

PROBABLY no fractures have in the past given rise to more anxiety or have been more uncertain as to their end results than fractures of the neck of the femur, for they are fractures in which non-union frequently occurs. Many reasons have been given for this: (1) The fracture occurs chiefly in the elderly; (2) it is often at first unrecognized; (3) the head of the femur has a poor blood supply; (4) the fractured surfaces are bathed by synovial fluid. It is now, however, widely held that while these may be predisposing causes, the real reason for non-union is the lack of adequate apposition of the fractured ends of bone and the lack of adequate fixation for a long enough period.

Types of fractures.—Fractures of the neck of the femur have been classified in several ways, but for practical purposes they can be divided into two groups: (1) sub-capital fractures, i.e., intracapsular fractures; (2) basal fractures, i.e., fractures through the base of the neck which may be partly intra- and partly extracapsular. Either type may be impacted, and in cases of impaction, or partial impaction, the fact that a fracture has taken place may not at first be recognized either by the medical attendant or by the patient, who may be able to walk. An impaction may be simulated by a partial locking of the fractured fragments, in which case it is certain ultimately to give way.

The sub-capital type is the more difficult to treat, and the one more likely to result in non-union if the treatment is inadequate.

Displacement.—In considering the treatment of the condition, the first essential is to visualize the displacement. In the typical case, that without impaction, the limb is shortened, adducted and externally rotated. Shortening may be caused partly by the injury itself, or may be produced and maintained by the pull of the gluteal muscles attached to the great trochanter, and of the muscles of the thigh. Adduction is caused by the adductor muscles, which have to act without their normal fulcrum, and which, in an attempt to support and fix the limb, pull the shaft of the femur inwards. External rotation is caused by the weight of the limb, which naturally falls outwards when the patient is lying. If impaction or partial impaction or locking of the fragments has occurred, the displacement will naturally be modified accordingly. The position would be shown by an x-ray photograph, and if possible a lateral view should be taken. For this purpose a curved cassette may with advantage be used.

Treatment.—The first object of treatment is to correct the shortening and to restore the normal alignment. As the displacement is one of adduction and external rotation, it follows that treatment must aim at reversing this process, and after overcoming the shortening by traction must abduct and internally rotate the limb. All authorities are agreed about this, but it is on the methods both of reduction and of fixation that divergencies of opinion occur. It was Royal Whitman who first recognized the fact that success in the treatment of this fracture, as of all fractures, depends primarily on obtaining a correct alignment of the fragments and adequate fixation. Two methods of attaining this object will be mentioned.

METHODS OF TREATMENT

(1) The abduction and plaster fixation method of Whitman. (2) Open operation.

(1) *Whitman's method.*—Whitman observed that if, under anaesthesia, the upward displacement of the shaft were reduced by direct manual traction on the limb, slight inward rotation and abduction of the limb to

the normal limit would place both fragments in the same plane. At the same time the tension of the capsule incidental to abduction would oppose and force the fragments into direct and resistant contact, which in fractures of the intracapsular type is essential for repair. He considered that the security assured by bony contact and capsular tension would be still further supplemented by the contact of the trochanter with the side of the pelvis; in sub-capital fractures, by inclusion of the fracture line within the acetabulum, and finally by relaxation of the muscles. He contends that in this way the natural mechanics of the joint are used both to fix the fragments and to correct the deformity.

In detail, the method is as follows:—Where a special table is not available, the patient, having been anaesthetized, is placed on a pelvic support, his shoulders raised on a box of equal height. Two assistants make manual traction on the extended limbs, drawing the perineum firmly against the bar of the pelvic support on the injured side. The surgeon meanwhile lifts the thigh upward if it is below the plane of its fellow. Both limbs now being extended and under manual traction, that on the injured side is slightly rotated inwards, and they are then abducted to the full extent, the sound side first, in order to demonstrate the normal range and to balance the pelvis. Measurements are made to ensure that the shortening has been corrected, and if possible x-rays, antero-posterior and lateral views, are taken to confirm the position. Plaster of Paris is then applied, including the foot, with the limb in

Fig. 1.—(a) Line of fracture; (b) Smith Petersen pin *in situ*; (c) cross section of pin.

complete abduction, full extension and slight inward rotation. When the spica is firm, the patient is placed in bed, the head of which is raised one or two feet. As soon as possible he is turned completely on to his face, and this is repeated from time to time in order to avoid the possibility of bed sores. This spica is retained for probably about six months, *i.e.*, until it can be demonstrated by x-ray that union is firm. Full weight-bearing is not permitted until free painless movements indicate stability and repair. When the plaster is removed the patient should remain in bed for a few weeks for muscular re-education. It is of vital importance that premature weight-bearing should not be allowed, as this will prevent union and cause a deformity.

A method for attaining and holding the position of abduction and internal rotation as advocated by Whitman, without the use of a plaster spica, has been devised by Roger Anderson. He applies a plaster case to the affected leg below the knee, and to the sound leg as far as the middle of the thigh. A special apparatus is attached to each plaster, and by the use of skeletal traction the correct position is attained, the sound leg being used for counter traction.

(2) *Open operation.*—In order to reduce the length of recumbency necessary and to make more certain of good apposition and union, some surgeons advocate open operative fixation of the fracture. For many years bone grafts and pegs have been used in the exceptional case. Smith Petersen, however, has evolved a method in which he uses a special steel pin which in his opinion should be the routine way of treating all fractures of the neck of the femur. The

principle is to correct the deformity of the bone by manipulation and traction and to expose the fragments

Fig 2

Fig. 2.—Old-ununited fracture.

so that they can be seen clearly. The special steel pin is then inserted through the great trochanter along the neck and into the head of the bone (figure 1). Wires are sometimes used first to act as directors, and their position checked by x-ray. After this operation some patients commence walking as early as fourteen days, though many advocates of the method think it is inadvisable to allow weight-bearing until consolidation of the bone has taken place. The great advantage of the operation is that no other fixation is necessary, plaster of Paris is dispensed with, and free movements

Fig 3.

Fig. 3.—Old-ununited fracture after Lorenz bifurcation operation.

of the hip and knee are possible from the first. The method is sometimes used in the earlier cases of non-union. It is then necessary first to freshen the fractured ends of bone.

OLD CASES

It is likely, however much the methods of treatment may be improved in the future, that there will from time to time be some cases of non-union (figure 2). Patients who have this distressing condition complain of constant pain and weakness of the leg, and have the deformities of adduction and external rotation with shortening of the limb. Their treatment presents a real problem. Some surgeons expose the fractured ends of bone, freshen them and insert a bone peg through the trochanter. Whitman removes the femoral head, and detaching the great trochanter, re-attaches it lower down on the shaft of the femur in such a way as to enable the neck of the bone to take up a position in the acetabulum. The hip is then fixed in a plaster spica.

Of all operations, the simplest, and one which merits very careful consideration, is an osteotomy of the femur. The osteotomy may be of two types:

(1) Lorenz's bifurcation operation (figure 3).—The shaft of the femur is divided below the small trochanter, and is displaced inwards so as to lie against the pelvis at the lower border of the acetabulum. The limb is fixed in moderate abduction in plaster, and when united, this ensures that the weight is partly taken off the site of fracture and transferred to the pelvis directly. It also prevents the shearing effect which carrying the body-weight on the affected limb causes in the presence of non-union, and it may result in union of the fracture.

(2) Pertrochanteric osteotomy (figure 4).—The object of this operation is to form a buttress for the fracture. The femur is divided just above the small trochanter, and the shaft is displaced inwards so that the

FIG. 4.

Fig. 4.—Old-ununited fracture after pertrochanteric osteotomy with displacement of shaft inward to support line of fracture. (a) Line of fracture; (b) position of osteotomy.

upper end lies below the line of fracture. The leg is fixed in plaster in abduction for about four months, until union of the osteotomy is sound. Like the Lorenz operation, it stabilizes the hip-joint by preventing the weight of the body from being borne by the fractured surfaces. It may result in union of the fracture.

COMMENTARY

In the treatment of fractures of the neck of the femur the choice lies between the abduction and plaster method of Whitman and the open operation. The Whitman method still holds the field as that of widest application. Careful attention to detail and the use of lateral x-rays should increase the percentage of good results. Smith Petersen's method is still on trial, and its use will always be limited to those surgeons who specialize in this type of work.

In the old case of non-union the simplest way of relieving symptoms is to perform an osteotomy either of the Lorenz or pertrochanteric type, though the reconstruction methods of Whitman and others all have their special applications.

The Anæmias of Nutritional Deficiency, Ætiology, Diagnosis, Treatment and Prevention

By G. R. MINOT, M.D.

(From the *Journal of the American Medical Association*, Vol. CV, 12th October, 1935, p. 1176)

THE development of information concerning anæmia during the past decade has permitted the clear recognition that this condition often may be dependent on defective or deficient nutrition. This idea, however, is not new; for example, in 1651 was written by an anonymous author '[Chlorosis is] chiefly found in young maidens who.....foolishly feed upon trash'. Wide gaps in our knowledge remain and complete information concerning the mechanism of producing anæmia associated with nutritional deficiency must be obtained in the future, but at present one can recognize that anæmias may arise because of a lack or non-availability in the body of at least three classes of dietary substances: (1) iron, (2) vitamin C and (3) a mysterious substance contained abundantly in liver and, to a less extent, in certain other organs which, if absent, makes normal blood formation impossible, and anæmias of the so-called pernicious type ensue.

ÆTIOLOGY

The anæmias due to a deficiency of the material effective in pernicious anæmia are macrocytic, but all cases of anæmia with the red blood cells averaging larger than normal are apparently not due to a shortage

of this material. The effective substance or substances are perhaps becoming less mysterious as the result of the work of West and Dakin and of Jacobson, Subba Row and Fiske and appear to bear some sort of relation to the vitamin B complex. A deficiency of the material effective in pernicious anæmia may be brought about in several ways and undoubtedly more than one mechanism is operative in many cases. It is to be noted that the normal individual, as Castle has shown, obtains the material from a variety of dietary sources because by means of gastric digestion he can derive it from certain precursors which the food contains. Muscle meat, eggs, rice polishings and yeast contain the dietary factor, which is thus associated with a number of sources of the vitamin B complex but is not identifiable with any of the known portions of this complex. The exact nature of the gastric digestive factor is unknown, but it is not one of the well recognized gastric secretory components. It is probable that the gastric reaction proceeds somewhat according to the law of mass action, so that a little of the gastric factor in the presence of a large amount of the food factor, and *vice versa*, may produce material sufficient to meet to a significant degree the demands of the body. A lack of the digestive power will result in shortage of the necessary substance, which is what happens in virtually all cases of Addisonian pernicious anæmia. The same state of affairs may occur from total ablation of the stomach or its destruction from cancer, and sometimes in pregnancy. If there is little food containing the precursors there is also a deficit of the substance, as may arise in tropical macrocytic anæmias, including sprue, in pregnancy and perhaps in certain cases of pellagra. Faulty absorption of the formed material also can create a deficit of it in the body, as takes place in certain cases of coeliac disease, advanced sprue and rare instances of intestinal stenosis and multiple anastomosis, and a deficit may also result from prolonged diarrhoea. In liver, kidney and certain other organs the potent material exists preformed, and that is why these organs, in contrast to beefsteak, for example, are effective in pernicious anæmia.

Defect of the internal or intermediary metabolism of the effective material may perhaps play a rôle in the production of some cases of macrocytic anæmia. There is no real proof of this disorder, but the variation in the injected dose of the same liver extract required for the maximal effects in apparently similar cases suggests, among other reasons, the existence of such a condition. This mechanism has been speculated on to explain, for example, the macrocytic anæmia associated with liver cirrhosis, a condition which may occur in a patient with pernicious anæmia. Wilkinson has called certain cases of anæmia with megalocytosis not responding to liver extract 'achrestic anæmia (from $\chi\rho\eta\sigma\theta\alpha\iota$, to utilize)'. However, because an anæmia does not respond to liver it does not imply that there is inability to utilize or mobilize the material needed by the pernicious anæmia patient. Such a condition may exist, but by similar reasoning one would surely not deduce that because cases presenting purpura did not respond to orange juice they were cases of scurvy failing to utilize vitamin C.

Deficiency of vitamin C (cevitamic acid) leads often to anæmia of a normocytic or slightly macrocytic type. This anæmia, when uncomplicated, responds to this substance and not to liver extract or iron.

The 'iron' deficiency anæmia or anæmias that at present may be thought of as representing this condition are hypochromic and usually microcytic. Hæmoglobin deficiency is the feature, and this may arise from lack of material other than iron needed to build the hæmoglobin molecule, so that all or some of the conditions referred to for clarity as 'iron' deficiency anæmia may be primarily dependent on some more subtle or extensive defect. They can, however, be cured or permanently arrested by iron therapy.

These anæmias can arise because of an inadequate diet or faulty absorption of iron. The latter condition

may depend on various factors altering the motility and secretions of the gastro-intestinal tract and the composition of its contents. Improper mastication and diarrhoea may be responsible and gastric achlorhydria can play a rôle in respect to faulty absorption. An improper utilization of hæmoglobin-forming materials may also produce these anæmias. Information regarding this mechanism is scanty. Certain substances, such as chlorophyll, apparently can enhance the utilization of iron, but little if anything is known regarding the regulation of iron metabolism as compared, for example, with calcium. Loss of iron together with other blood building material is also a common cause of these anæmias. This happens from blood loss, especially of chronic nature, and by the fœtus obtaining its supplies from the expectant mother.

More than one of these mechanisms is apt to be operative in a given case as, for example, in pregnancy, in which inadequate diet, achlorhydria or otherwise altered digestion and the presence of the fœtus are all likely to play a rôle. These anæmias, which respond to iron, are especially frequent in women before the menopause. The part played by menstruation is interesting to speculate on. 'Idiopathic' hypochromic anæmia, both of the very mild and of the severe long-standing type, belongs in this group, as does the now rare condition chlorosis. 'Iron' deficiency anæmias are also common in infants and children, in pregnancy and in individuals with 'chronic indigestion', chronic ill health and anxieties as their presenting symptoms. Many cases can be attributed to repeated loss of blood, and this factor, operating together with others, is very frequently observed.

FACTORS ASSOCIATED WITH IRON DEFICIENCY AND MULTIPLE DEFICIENCY

Iron alone cannot make hæmoglobin or red blood cells, and there are other blood building factors that may be deficient, particularly when 'iron' deficiency exists; for example, material contained in that fraction of liver separated by Whipple, which is effective in anæmia due to repeated losses of blood. This material is distinct from the material effective in pernicious anæmia. Indeed, the exact rôle that many elements of the diet play in the manufacture and maintenance of normal blood is yet to be learned. Whipple has, however, placed on a secure quantitative basis the influence of food on blood regeneration. The strikingly beneficial effect of proper doses of iron in what may be conveniently considered 'iron' deficiency anæmias certainly may not be wholly dependent on deficiency of this element. Much more information is desirable.

There is very little evidence that in man deficiency of copper plays a significant rôle in the production of anæmia. It may perhaps do so occasionally in infants. In human anæmia the copper of the blood is usually increased. While it is true that in young children, when iron is supplemented by copper, it sometimes enhances the rate of hæmoglobin formation, in adults copper therapy apparently is very seldom of value. These remarks do not detract from the important observations of Hart and Steenbock concerning the rôle of copper in iron metabolism, as shown by studies on certain experimental animals. Traces of copper are usual in pharmaceutical iron preparations and thus are given when iron is prescribed. It is not difficult to create serious copper poisoning by administering relatively small amounts of copper.

In man, dietary deficiency is seldom confined strictly to one factor, nor are the results of disturbances of gastric secretion, of defects of intestinal absorption, or of utilization necessarily concerned in only one type of metabolic process. The combined deficiency of 'iron' and the material effective in pernicious anæmia is not rare in the same individual. Other double and multiple deficiencies occur in patients with anæmia, but usually one of the deficiencies is outstanding. Whole liver, owing to a factor or factors not effective in pernicious anæmia, as well as iron, can regenerate the blood in the anæmia due to chronic blood loss. The

main effect of liver cannot be attributed to its iron content. It is circumstances like these that make it necessary to appreciate that the term 'iron' deficiency does not adequately describe all cases placed under this heading. The withdrawal from the tissues of material to make hæmoglobin, the influence of substances or physiologic mechanisms on the utilization of iron and hæmoglobin building substances must be studied further before there is final knowledge concerning 'iron' deficiency anæmias. In observing the influence of specific substances the supplementary effect of diet must not be forgotten, and it is obvious that an adequate diet should be taken by everybody.

INHIBITORY FACTORS

The mechanisms outlined for the production of nutritional deficiency anæmias are the same as those for the production of any dietary deficient condition. In addition, it is important to appreciate that there are factors which may inhibit nutrition and intensify a deficient state. Thus, in anæmia they inhibit blood formation and hinder the action of such therapeutic agents as liver extract and iron. Such factors are infection, serious damage to vital organs, arteriosclerosis and increased or altered metabolism. It also must be recognized that the body should always contain an appropriate reserve supply of nutrient substances readily available for extra demands. The individual whose body has received for a long time only just enough of a nutritional factor, such as a vitamin or mineral, to maintain health may be precipitated into the zone of partial deficiency with the advent of infection. In this instance no clinical signs of deficiency are apt to become apparent. If, however, the individual's nutrition remains for some time close to the level permitting the appearance of symptoms readily attributable to deficiency, and infection ensues, then anæmia, polyneuritis, scurvy or some other nutritional defect is likely to become manifest according to the exact circumstances in the given case. Knowledge of partial deficiency states or nutritional instability in man is meagre. It is highly desirable to obtain information as to how to determine precisely such states; only a few hints have been given. It is a problem of concern to the health of the world.

DIAGNOSIS

One cannot, of course, adequately treat a patient until a detailed diagnosis has been made. The hasty administration of both liver and iron before the actual needs of the patient have been intelligently considered may lead to embarrassing circumstances. If the anæmic patient does not have pernicious anæmia, how unfortunate it is to have prescribed both liver and iron and later on when the blood is approximately normal to be unable to determine whether or not he should continue with liver for the rest of his life.

A catalogue of conditions that may be thought of in establishing diagnoses of anæmias due to or associated with nutritional deficiency will serve no useful purpose. A few aspects of diagnosis, however, will be considered. The concept of establishing a diagnosis of a deficient state rather than simply of anæmia will probably lead to earlier diagnosis and better treatment. Pernicious anæmia should be diagnosed earlier than it usually is. It is often not diagnosed until the patient has had definite symptoms for a year or more attributable to a deficiency of the material he needs. Early diagnosis and complete treatment are important in order to prevent the development of neural lesions and to save suffering. The disease should not be allowed to progress until one sees the typical textbook picture of the blood, a patient with a palpable spleen and a grapefruit coloured complexion or other signs of pronounced relapse or long-standing illness. Early diagnosis implies detailed attention to the patient's history and being alert to detect the disease in patients with 'chronic indigestion', a tendency to loose stools, atrophic or recurrent sore tongue, slight signs of neural involvement, achlorhydria and slight macrocytosis of

the red blood cells. The use of the tuning fork to detect impaired vibration sense and careful scrutiny of a blood smear are simple but invaluable aids to diagnosis. Multiple sclerosis, spinal cord tumours and other neurologic conditions must be excluded. The symptoms of *anæmia per se*, such as palpitation, dyspnoea and impaired kidney function, for example, should not cause an established diagnosis of heart or kidney disease. The *anæmia* associated with nitrogen retention may be macrocytic, and lesser degrees of increased mean corpuscular volume occur in liver disorders and in other conditions than the macrocytic *anæmias* responding regularly to liver and allied therapy.

A common error is to diagnose pernicious *anæmia* when a patient has chronic *anæmia* due to a fundamental depressed dysfunction of the bone marrow for which little can be done. This happens especially when the colour index is not decreased and large red cells are present. This state of affairs may occur in so-called idiopathic chronic 'aplastic' *anæmia* and in comparable states arising from benzene and other poisons. Under such circumstances the correct diagnosis may also be one of the types of leukaemia without elevation of the white blood cells, occasionally Hodgkin's disease with invasion of the bone marrow and involvement of the bone marrow with tumour metastases or tuberculosis. Idiopathic chronic purpura hæmorrhagica (thrombocytopenic purpura) is to be distinguished from these cases.

Cases called idiopathic chronic 'aplastic' or aregenerative *anæmia* may represent several conditions, and more knowledge concerning this group is much to be desired. Some, if not all, cases termed chronic malignant neutropenia, panmyelophthisis, hæmorrhagic aleukia and achrestic *anæmia* belong to this group. In these chronic cases the bone marrow may vary widely in appearance from an anatomic fatty aplasia to marked hyperplasia with physiologic inadequacy, either complete or with evidences of attempted regeneration of blood. Although usually there is a slow, progressive decrease of all three formed elements in the peripheral blood, which originate in the bone marrow, occasionally a slight and very rarely a marked temporary 'spontaneous' remission may occur, thus simulating the natural course of pernicious *anæmia*. Bleeding associated with reduction of blood platelets is more common than in pernicious *anæmia*, and persistent leukopenia is a feature. Macrocytic *anæmia* is the rule, but liver extract, even when given in very large doses parenterally, calls forth no worth while response, although rarely a weak response results which is only temporary. Repeated transfusions of blood offer the best palliative treatment. Gastric achlorhydria is only sometimes present, and signs of involvement of the neural system, such as occur in pernicious *anæmia*, are absent. Rarely is the tongue atrophic, and distinctive signs of glossitis do not seem to occur. Fever, simulating that seen in untreated pernicious *anæmia*, increased pigmentation of the skin and terminal ulcerations in the mouth are not unusual.

The occurrence of concomitant conditions must not cause the diagnosis of pernicious *anæmia* or *anæmia* associated with nutritional deficiency to be overlooked. Chronic arthritis is common in pernicious *anæmia* and may lead to considering neural symptoms due to joint disease. Gall-bladder disease occurs in about 25 per cent of cases of pernicious *anæmia* and in such cases operations have been done without an appreciation of the existence of pernicious *anæmia*. The coincidence of diabetes mellitus and pernicious *anæmia* in the same individual, although rare, is more frequent than can be accounted for by chance. I have noted that the incidence of diabetes in relatives of pernicious *anæmia* patients is distinctly more common than in a control group. Such relationships offer interesting speculations.

In many cases infection may be the chief cause of *anæmia*, and removal of the cause the important aspect in treatment. In such cases, however, defective nutrition may arise and intensify the *anæmia*, and this aspect

of diagnosis should not be overlooked. Thus iron therapy may be delayed when it would be distinctly effective, especially as the infection subsides.

The occurrence of slight splenomegaly in 'idiopathic' hypochromic *anæmia* and in some cases of chronic *anæmia* arising in children has led to the diagnosis of splenic *anæmia* and splenectomy, when full doses of iron would have cured the condition and permitted the enlarged spleen to recede behind the ribs.

Menorrhagia may be a symptom of 'idiopathic' hypochromic *anæmia* as well as a condition acting to intensify the defective nutritional state. The wrong diagnosis may lead to only local treatment of the uterus when full doses of iron will cause the menstruation to become normal.

Removal of 'hookworms' alone will not alleviate the *anæmia* so common in patients infected with these parasites. The defective nutrition usually present must be recognized. Full doses of iron will often promptly restore the blood to normal, which will take place more rapidly if the diet is also made complete.

TREATMENT

In prescribing for *anæmias* arising from nutritional deficiency, the realization that one is treating a patient with a generally deficient nutritional state should be paramount. The *anæmia* is often but one symptom of the defective nutrition. For example, in pernicious *anæmia* the tongue and neural symptoms are dependent on deficiency, and in 'idiopathic' hypochromic *anæmia* dystrophy of the nails and alteration in the mucosa of the uterus, leading to abnormal bleeding, appear to be of nutritional deficiency origin. The atrophy of the papillæ of the tongue in the latter condition, as well as certain other manifestations, quite probably are not due to iron deficiency *per se*, but they may be decreased by iron therapy, perhaps because of the better appetite that ensues, which results in partaking of a better diet. Here again, however, more knowledge is needed, for example, concerning the possible interrelated effects of iron and the vitamin B complex.

The object of treatment is not only to eradicate symptoms or place them under control, but also to restore reserve supplies and the patient's nutritional state to normal for the rest of his life. The aim must be not only to return the hæmoglobin and red blood cells to normal levels and keep them there but also to maintain the blood normal in all respects so that the colour index, cell size and volume are normal. But the amount of material necessary to accomplish this may be less than the amount needed to prevent the development or progress of other disorders, such as neural manifestations in pernicious *anæmia*—an important point to appreciate. With liver extract, stomach or other preparations effective in pernicious *anæmia*, the common error is to give too little, particularly after the blood has become approximately normal. Each case is an individual problem. Indeed, the amount of parenterally given liver extract required in macrocytic *anæmia* may vary tenfold. The variation for the optimal dose of iron is apparently less. The cases requiring the largest amount of iron are severe ones of long-standing 'idiopathic' hypochromic *anæmia*, while among the cases responding maximally to one-third or even one-fourth of this amount are those of chronic blood loss without achlorhydria or chronic dietary or digestive disorder. In the former condition maintenance of iron therapy is often necessary to prevent relapse; in the latter state the patient is truly cured when the blood and body reserves become normal and he continues to take a satisfactory diet. In practice it is wise to use a large dose, one certain to cover the patient's requirements. Recovery should not be delayed by economy of a relatively inexpensive remedy. To give somewhat too much iron does no harm, except in rare instances of distinct intolerance.

Remedial substances for many nutritional deficiencies may be given parenterally as well as orally. Thus, optimal amounts can easily enter the body and defective absorption be overcome. Some of these substances,

such as liver extract, are in the range of from fifty to hundred times as effective by the parenteral route. This route is the one of choice for liver extract in sick individuals, those requiring large doses or those with spinal cord lesions. The procedure is economical and convenient, and it gives assurance of sufficient material entering the body on selection of an appropriate dose for the given patient.

There is no need for the parenteral use of iron except, perhaps, in an extremely rare case. A distinctly effective daily dose parenterally is close to a toxic dose. Thus the injection of small doses every few days is to be deplored. The problem of what preparation of inorganic iron or liver extract or allied substance to use resolves itself into choosing any one of many effective preparations and giving an appropriate amount of that particular preparation for the given patient. The daily dose of the iron salts is variable, the maximum for iron and ammonium citrate being in the range of 6 gm., and of ferrous sulphate in the range of 1 gm. Among available liver and allied products there is a wide difference in potency when compared with whole calf's liver or with the amount of material from which an extract originally came. The use of liver extract and iron together should be judiciously decided. The development of hypochromic red cells or a lag in haemoglobin production in a patient with pernicious anaemia calls for both. Some patients, particularly benefited by iron, may perhaps have recovery speeded by the use of these two substances. The effectiveness of suboptimal doses of iron with liver in hypochromic anaemias may be no greater than an optimal dose of iron. The addition of Whipple's liver factor to iron may be of distinct value in certain cases. The important matters to bear in mind are that either liver extract of the type effective in pernicious anaemia or iron will be the chief agents to use and that combinations employed at random will often waste the patient's money and may prevent an understanding of the needs of the patient. It must be remembered, also, that treatment means still more than administering substances to offset deficiency. Satisfaction with great improvement in the patient is not enough; he must be made as well as possible. All aspects of the case must be attended to, including the individual's manifold problems of thought and action.

PREVENTION

The prevention of illness is much simpler and more desirable than successful therapy of the sick man. A diet nicely adjusted with respect to all its constituents at an optimum—not a usual—level permits development of the organism to proceed uninterruptedly and the health of the individual to be maintained as near

the optimum as possible. Ideally, nutritional defects should be detected when individuals begin to pass into the zone of suboptimal nutrition and thus prevent the development of disease. At present this state is usually difficult to prove but often can be suspected, particularly by a detailed study and careful evaluation of the dietary history. The physician should appreciate when he prescribes a diet for one reason or another for more than brief periods of time that it must be complete. It is not very rare to be able to detect nutritional disturbance due to prescribed diets as, for example, for peptic ulcer and chronic nephritis.

Certainly a good diet throughout life will aid in the prevention of anaemia. Consideration of such matters as are mentioned later will do likewise. A careful study of near relatives of a pernicious anaemia patient may reveal in one or more of them gastric achlorhydria with or without slight abnormality of the blood, although the individual considers himself well. In view of the familial incidence of pernicious anaemia, the presence of achlorhydria in such a case may indicate a 'latent' one of pernicious anaemia. Liver therapy for that person may prevent, perhaps, the development of distinctive disease. The frequency of hypochromic anaemia during the first year of life in babies born of anemic mothers may be minimized if such infants are given small doses of iron as a routine procedure. The development of hypochromic anaemia in pregnancy is common. Iron administration frequently can prevent the development of hypochromic anaemia in pregnant women and thus aid to prevent anaemia in the child. Anaemia will also become less frequent if an attitude is taken that all edentulous individuals must have properly fitted false teeth and that the diet for all patients with 'chronic indigestion' should be very carefully regulated. It is of great importance to recognize the frequency with which repeated losses of menstrual blood in slight excess of normal lead to anaemia, as well as repeated small losses of blood from any source. Attention given early to this state of affairs will also minimize the occurrence of anaemia.

CONCLUSION

The practice of prevention is the ultimate goal of the physician. Success often depends on inherent interest, on attention to detail and on an understanding of the etiologic and physiologic mechanisms involved in a given case. There is much more to be learned about the anaemias and nutrition. With the progress of knowledge there should be much less suffering from disorders due to, or associated with, nutritional deficiency.

Reviews

MANSON'S TROPICAL DISEASES: A MANUAL OF THE DISEASES OF WARM CLIMATES.—Edited by P. H. Manson-Bahr, D.S.O., M.A., M.D., D.T.M. & H. (Cantab.), F.R.C.P. (Lond.). Tenth Edition. Revised. 1935. Cassell and Company, Limited, London. Pp. xx plus 1003, with 22 coloured plates, 15 half-tone plates, 381 figures in the text, 6 maps and 38 charts. Price, 31s. 6d.

We have for some time thought that the vast subject of tropical medicine should be split up; it has seemed to us to be an impossibility for one man to write accurately on such a diversity of subjects, amongst which he must of necessity only have had any significant practical experience of a very limited number. Yet, in the tenth edition of this book, Dr. Philip Manson-Bahr has achieved a most remarkable success, and, though we refuse to retreat from our position, we do not admit to having suffered a reverse.

First of all, one is impressed by the enormous amount of work that must have been put into this book; every section has been most carefully rewritten, and on each subject all the work which has been done during the six years that intervened between the ninth and tenth editions has been most carefully weighed up and the important observations have been skilfully interwoven with the best of the material of the previous edition. More than this, it is obvious that the author has had personal contact with those who have had first-hand experience of the subjects about which he writes. The author in his preface says that no man can be an expert on the diversity of subjects that tropical medicine presents; this might be said of the judge on the bench with reference to many cases he has to try in which various experts give evidence, but we know that the man with personal technical knowledge is not necessarily the best judge. Dr. Manson-Bahr has

proved himself a very good judge; in the position he holds at the School of Tropical Medicine he has been able to cross-question witnesses and to elicit details that 'evidence on commission' could not possibly provide; he has taken full advantage of this opportunity and has presented to us a most excellent summing up.

As we are told in the preface, in order to make room for new matter a certain amount of jettisoning has had to be done, and for this purpose the author selected what he calls 'non-essential scientific matter in the realm of medical zoology'. Whatever this may be, we did not miss it, and, though we have not been curious enough to compare the last two editions page by page, we have noticed that the present edition is increased by about a hundred pages; it has now reached its thousand pages which is about the limit for a single volume. Whether matter is essential or non-essential will always be a question for the decision of the individual reader, but, lest it should be thought that some of the very useful details of laboratory technique, and the descriptions and illustrations of protozoa and helminths have been omitted, we will mention that they have not; they still form an important feature of the book and make it a much more complete book of reference for the worker in the tropics than certain other books on tropical medicine that deal with the clinical side only.

We have of course certain criticisms to make. We cannot understand why the author has only devoted two lines to the Indian form of endemic typhus whereas to the Malayan forms, described much later, he has devoted a section. Fifteen years ago such an attitude might have been justifiable, as there were many who thought that the Indian endemic typhus that was described in 1917 was largely a figment in the imagination of one observer. There is now abundant proof that this observer was right, and, even if the aetiology has not been worked out as satisfactorily, as in other countries such as Malaya, the diagnosis of a large number of cases from many parts of India, based on irrefutable serological evidence, has shown the widespread existence of this disease.

In this same section the author says 'the disease known as typhus has two main manifestations—the first and better known is *true typhus*—a louse-borne disease of great communicability from one person to another in times of overcrowding amongst an unclean population, and characterized by its tendency to form epidemics; the second (*endemic typhus*), a disease primarily of rodents which is transmitted from rat to man by rat-fleas'. In the book the above sentence is separated into two parts by a table which demonstrates very clearly that the generalization is not justified, as the table shows that other rodents, besides the rat, and other animals have been incriminated as carriers and a variety of insects as the vectors. It would have been so easy to have included these in the generalization.

A subsequent reference to typhus as a louse-born disease is obviously a misprint.

In our review of the last edition we objected to the statement that kala-azar, 'unlike malaria, shows a predilection for the acclimatized—the natives'. The sentence still remains. It is certainly not true in India, as Europeans living in the highly endemic areas in Calcutta were proportionately just as frequently attacked as were Indians. Then, again what does the author mean by *natives*? Coolies that have come from over a thousand miles away to work in the tea gardens of Assam are certainly not natives of Assam (they are natives of somewhere of course, so are we all!), and they have been shown to be very susceptible. On the other hand another statement regarding the Wassermann reaction in kala-azar, to which attention was drawn, has been modified and corrected.

In referring to the nasal infections demonstrated by Forkner and Zia in China, the author misspells Forkner's name; but this is possibly a misprint as the name appears correctly spelt elsewhere.

We must repeat our protest against the illustration of a case of kala-azar on page 153, because it is a

caricature, not a typical example. Further, in our experience cases even approximating that degree of splenic and hepatic enlargement are more often not kala-azar. We must also initiate a protest against the new illustration on the opposite page; in the first place it doesn't show anything at all except a pair of legs. Secondly, we do not think that the condition that it was meant to depict (we have seen a painting of the same pair of feet in the Wellcome Museum) is a characteristic of kala-azar in the European. In the Indian, particularly in the fair Indian, and in the Anglo-Indian, even those with a very small percentage of Indian blood, there are wide variations in the pigmentation in different parts of the body, and the parts subject to pressure are often hyperpigmented.

The suggestion is made that, following on the observations of Hu and Cash that parasites can be found in the skin in kala-azar cases, a diagnosis might be made safely by cutting out a piece of skin and examining it for leishmania. We have seen a section of skin from a case of kala-azar showing leishmania, but we know from experience that it is a very unsatisfactory method and in 20 consecutive cases of kala-azar we failed to demonstrate leishmania by this method; it is of course the routine method of diagnosis of dermal leishmaniasis. On the other hand, the author has underestimated the value of examination of the peripheral blood; the parasite can be found in at least 60 per cent, and not 20 as he says, and not only in Assam and Madras but in any of the endemic areas in India.

In the paragraphs on dermal leishmaniasis, a little confusion has arisen. There is a xanthoma form, known as *Xanthoma tuberosum multiplex*, which is quite unmistakable, and in which the parasites have been observed in the peripheral blood (figure 36). In the first place, we, the late Colonel Acton and the reviewer, did not describe any condition as *Xanthoma tuberosum multiplex*, but we described a xanthoma (on account of its colour) type, which Colonel Acton pointed out resembled the condition described by dermatologists in other countries as *Xanthoma tuberosum multiplex*. Secondly, parasites have not been found in the peripheral blood in this condition any more than in any other type of dermal leishmaniasis; actually out of a very large number examined the parasites have been found in the blood in two cases only. Thirdly, figure 36 is not a photograph of a case of the xanthoma type of dermal leishmaniasis but of the ordinary nodular type.

Despite the number of the points on which we differ from the author, we consider that this section on kala-azar provides an accurate summary of the subject, with surprisingly few omissions, considering that it has been condensed into 22 pages, and very few mistakes. Other sections, such as that on yellow fever, seem to us to be wholly excellent.

There are 37 plates, 22 of which are in colour; with one exception they are all useful and of a high standard of reproduction; plate XI is very crude. The index appears to be complete but it has one very annoying feature; if you look up *Malta fever*, for example, you find '(see Undulant fever)'. It would have cost very little extra trouble to have added '271', and it would save the reader from having to look up *Undulant fever*. Admittedly, under this last-named heading there are 36 sub-titles, but nine times out of ten all the reader wants is an indication of where the section begins. This is a small point but this omission has been one of frequent annoyance to the reviewer.

This edition is a better balanced and more complete book than the last one, and it would be difficult to give higher praise. It is larger by nearly a hundred pages but the price has been maintained at the same very reasonable level; this is obviously only possible on account of the thousands of copies that are sold. Altogether it is a very remarkable achievement.

WOMAN: AN HISTORICAL, GYNÆCOLOGICAL AND ANTHROPOLOGICAL COMPENDIUM.—By H. H. Ploss, M. Bartels and P. Bartels. Edited by E. J. Dingwall. Volumes I, II and III. 1935. William Heinemann (Medical Books), Limited, London. Pp. xiii plus 655 in volume I, Pp. xii plus 820 in volume II and Pp. viii plus 543 in volume III, with more than 1,000 illustrations in black and white and 7 coloured plates in three volumes. Price, £8 8s.

THIS book is a classic, which has already gone through eleven editions in the German language. The first edition appeared in 1885 and since that date it has had many editors and has been subject to a number of different environmental influences—we do not suppose that it was read openly by our late-Victorian forbears, but it was no doubt obtainable in those sinister little shops that specialized in rubber goods and were a characteristic feature of the west end of London but which have now largely disappeared as all their wares are now sold openly in shops of good repute; in those days it was probably bought by the medical student—who even if he did not understand German understood the pictures—covered with brown paper, labelled 'Chemistry', and locked away in his most secret drawer when it was not being read or lent to a friend, but to-day in the ultra-modern family it will no doubt be left about in the sitting room as the family photograph album used to be. These variations in the internal and external influences—its numerous editors and its progress from the stuffy shop and the locked drawer to the fresh air of the booksellers' window and the suburban front parlour—have had a liberalizing effect on the book, for which it can now be claimed legitimately that it has not been unduly prejudiced by one particular age and that it does not represent any one school of thought.

This is the first English edition. The text bears none of the stigmata of a translation, and curiously enough it is in the illustrations that the fact is betrayed. The editor has not made a direct translation from the last German edition but has also used the earlier editions, and has, as he says in the preface, taken certain liberties with the text and omitted and altered conclusions and opinions that recent investigation has shown to be incorrect. Further, he has made his own interpolations and added data from English sources to supplement figures from Germany and other European countries.

The theme is woman—in her infinite variety, as an organism whose morphology, whose cultural and uncultured characteristics, whose reactions to, and effects on, the medium in which she lives, and whose symbiotic habits have been carefully studied and are described accurately and with a wealth of detail. Emphasis has perhaps been laid on morphology and the anatomical features of the genital organs and the accessory sex characteristics, as the first volume contains more illustrations of female genitalia than the reviewer has hitherto seen between the covers of any book, medical or otherwise, but the whole subject is presented in a matter-of-fact manner and there is nothing unpleasant or suggestive in the text or illustrations.

It is of course not only anatomical features of the woman of all races that are dealt with, but the physiological and psychological characteristics. Sexual, ritual, marriage customs, the status of women in different ages and different countries, the history of prostitution, child marriage, midwifery and gynæcology through the ages, abortion, symbolism and mysticism of the puerperium, lactation, the climacteric, and a hundred and one other aspects of woman and her functions and activities form the chapter and section headings.

The book is a treasure house of knowledge, invaluable to the anthropologist, the gynæcologist, the sociologist, and above all the professional writer of pseudo-scientific pornographic literature. In it the practitioner will find detailed information about women that he ought to

have at his disposal and much else that he may conceivably turn to useful account, and he will not find this information collected together in any other book; it is a unique publication.

L. E. N.

THE MODERN TREATMENT OF BURNS AND SCALDS.—By P. H. Mitchiner, M.D., M.S. (Lond.), F.R.C.S. (Eng.). 1935. Baillière, Tindall and Cox, London. Pp. ix plus 64, with 12 plates (2 coloured). Price, 5s.

ALTHOUGH the subject of burns and scalds is often relegated to the domain of minor surgery, the successful treatment of these distressing injuries is by no means easily accomplished. The advent of the tannic-acid method of treatment is a great improvement on the past, but its technique has to be mastered. For this reason alone, this excellent and authoritative monograph by Mr. Mitchiner will be welcomed by all.

This little book is divided into six chapters, of which the first three deal with general principles, first-aid treatment, prevention of shock and the final application of the compress. Special burns are considered in the next chapter. A consideration of the mortality of burns and scalds in chapter V provides interesting reading. Other uses of tannic acid are briefly outlined in the concluding chapter. The suggested first-aid outfit would be generally useful. An adequate bibliography and index are also appended.

The tannic-acid spray, with which every one is now familiar, has unfortunately its limitations. The author has suggested a simple and satisfactory method of treatment—equally applicable to both first aid and for a final dressing—the tannic-acid compress. It has been recommended as a safe, satisfactory and comfortable dressing for all burns, but it is not to be touched until the coagulum separates from the injured area. For a satisfactory stable lotion which will keep for at least two months, the author prefers a solution of 2 to 2.5 per cent tannic acid in 1/2,000 perchloride of mercury. In our hands, a similar solution, containing 1/1,000 acriflavine has given satisfactory results in spite of the two obvious drawbacks of staining of linen and formation of a softer coagulum. There is one inexplicable omission in this excellent book; there is no mention of a prophylactic dose of anti-tetanic serum. It has been our practice to use it as a routine method in our wards.

The printing, get-up and illustrations are all excellent. The general practitioner who buys this book will readily discover that he has made a profitable investment.

P. N. R.

THE HAIR AND SCALP: A CLINICAL STUDY. (WITH A CHAPTER ON HIRSUTIES).—By A. Savill, M.A., M.D. (Glas.), M.R.C.P.I. 1935. Edward Arnold and Company, London. Pp. vii plus 288. Illustrated. Price, 12s. 6d.

THIS is an unusual book in some ways for certain sections of it are devoted to the art and theory of hair dressing and an interesting chapter contributed by W. T. Astbury on the molecular structure and elastic properties of hair. These aspects of the subject although not strictly in the province of the dermatologist are of great value as they supply information not elsewhere obtainable which is of great assistance in the understanding and subsequent rectifying of certain hair conditions caused by modern hair dressing methods, for which he may be consulted.

The principal part of the book is naturally devoted to definite diseases of the hair and scalp and contains an immense amount of information; it is, however, rather badly arranged for some chapters are devoted to discussions of certain signs which necessitates frequent references backwards and forwards to other parts of the book where the diseases in which these signs occur are described; other chapters are devoted to diseases themselves. The book would be more easily read if

the symptoms and signs were all tabulated at the beginning and the remainder devoted to diseases only, this is a method which has been used in certain well-known books on general dermatology with excellent effect in simplifying the subject for a beginner.

The authoress has also attempted to emphasize the relative importance of the various diseases and signs by the use of three or four different styles of type, it is difficult to carry the relative value in one's mind while reading the book and rather spoils the appearance of many pages.

These criticisms are only in detail, however, for the information needed for successful treating and understanding of the various diseases of the hair and scalp is all in the book and it is only suggested that it might be still more valuable if better arranged. Special reference should be made to the chapters dealing with the scaly conditions of the scalp with or without true seborrhœa for in the chapters devoted to this very confused subject the authoress has effected a very clear and reasonable disentanglement, and this alone will make the book worth reading.

Like the beginning, the end of the book contains information not easily obtainable in a book on dermatology however comprehensive, and the penultimate chapter is devoted to hair dyes harmful and harmless, and the last chapter to the treatment of hirsuties the latter being given in detail. Finally there are a few useful formulæ.

The book is well produced and is printed on heavy art paper, which is not an objection in this case as the small size of the book does not make it too heavy. There are no coloured plates but the numerous photographic reproductions are excellent.

P. A. M.

A TEXTBOOK OF SURGICAL PATHOLOGY.—By C. F. W. Illingworth, M.D., F.R.C.S. (Edin.), and B. M. Dick, M.B., F.R.C.S. (Edin.). Second Edition. 1935. J. and A. Churchill, Limited, London. Pp. x plus 719, with 301 illustrations. Price, 36s.

MESSRS. ILLINGWORTH AND DICK are to be congratulated for bringing out a second edition of their admirable textbook of surgical pathology within three years of its first publication. As this new edition includes many interesting subjects of recent development, the authors have found it unavoidable to add slightly to the bulk of the volume. We have little doubt that this book will continue to maintain its high position in the surgical sphere all over the world, particularly amongst the English-speaking nations.

It will not be an exaggeration to say that this treatise is an embodiment of the pathological aspects of the British school of surgery. The first eight chapters deal with general pathology in relation to surgical conditions and the rest of the book has been arranged systematically in different sections each of which is full of all the modern ideas on the subject. The whole book has been written in a style which is at once impressive, easy to read, and stimulating, and one never feels it monotonous to go through its pages. A very noteworthy feature of the book is the inclusion, at the end of each chapter, of a well-chosen bibliography which, though not exhaustive, is undoubtedly comprehensive, and is likely to be very helpful to those in search of further information. The authors have also enriched this edition by including many new subjects. Special mention may be made of the section on diseases of the bone which has been thoroughly rewritten in the light of the recent developments, as also leukoplakia of the tongue, xanthomatosis of bones, granulosa-cell tumour of the ovary, the islet-cell tumour of the pancreas, post-traumatic osteodystrophy and the pre-natal muscular dystrophy.

While there can be no two opinions regarding the excellent way in which the book has been written and the wealth of information and new ideas which have been incorporated in it, we cannot but draw the attention of the writers to the following points.

The outstanding defect throughout the book is the poor quality of its illustrations, specially the photographs, which have failed to reproduce what they are meant to represent, and it is indeed difficult to find anything of the magnificent collections of the Edinburgh Royal College in these diagrams. Certainly the quality of the paper could have been improved for better reproduction.

We have failed to find any improvement in the chapter on actinomycosis which the authors have particularly mentioned in the preface. If they had left out the bacteriological aspect of the subject, many inaccuracies might have been avoided. Lastly, we think it would have been better had vague terms like 'tumour', 'cancers', 'ulcerous', 'alveolar carcinoma', 'epithelioma', 'endothelial sarcoma', etc., not found a place in a scientific book of such a high order.

M. N. D.

A TEXTBOOK OF FRACTURES AND DISLOCATIONS COVERING THEIR PATHOLOGY, DIAGNOSIS AND TREATMENT.—By K. Speed, S.B., M.D., F.A.C.S. Third Edition. Thoroughly Revised. 1935. Henry Kimpton, London. Pp. 1000. Illustrated with 1,042 engravings. Price, 50s.

THIS compendious production runs to 1000 pages with 1,042 illustrations. The word compendious is used in its literal sense; the work is a veritable encyclopædia in one volume on bone injuries and dislocations. On this account, and reason of its price, it is hardly likely to appeal to the average student in search of a textbook on fractures. Essentially a book for the specialist, it might find a place as a book of reference in Indian district hospitals where the occasional fracture, no matter how rare and peculiar, must be treated locally with every other kind of case.

From a perusal of publisher's lists it would appear that there is some risk of congestion among the works devoted to fractures. Life to-day however is attended by a greater risk of accident than ever before so that it is but a sign of the times. These books may be divided broadly into two classes. Those devoted to the exposition of a particular school of teaching, as for example, the recent excellent translation of Bohler's work by Hey Groves, and those more liberal in outlook which attempt to present the best from many schools of thought. This book belongs to the latter class and coming from the pen of a member of the Central Committee on Fractures of the American College of Surgeons it admirably fills the purpose of a comprehensive guide to the subject. It is evidently based on enormous personal experience and is consequently free from fads and inadequately tested ideas.

This is the third edition and those who know it in its earlier forms will find the revision has produced many satisfying changes. The futile habit of reproducing hundreds of indistinct radiographs in half-tone has been carefully avoided. In the comparatively rare instances where an x-ray film has been actually reproduced, it has been chosen with care, so that something more than the usual smudge is presented. Many hundreds of carefully prepared tracings have been substituted and these line drawings show all that must have been visible to the surgeon in the original films. It is doubtful however in spite of their excellence whether quite so many need have been included. They increase the size of the book without commensurate value to the purchaser. Figures 442 and 497 may be quoted as examples taken at random.

A very extensive literature is listed after each chapter, most of which will be out of reach of the reader in India. Unlike many American and foreign books however there is rather more than the usual meagre reference to English works and periodicals. The style is terse and to the point making for easy reading, the English being singularly free from those peculiarities we have learned to meet without surprise in books from America. Altogether a book which can be recommended to the general surgeon in this country who

requires something more searching than the usual textbook as a guide to this difficult and responsible branch of surgery.

H. R. R.

THE FOOT.—By Norman C. Lake, M.D., M.S., D.Sc. (Lond.), F.R.C.S. (Eng.). 1935. Baillière, Tindall and Cox, London. Pp. vii plus 330, with 95 illustrations. Price, 12s. 6d.

In this interesting monograph, the author has dealt with an important subject, which generally receives but scant attention in an over-burdened medical curriculum. It is intended for the practitioner and the general surgeon and is, in short, a manual dealing with the evolution, anatomy, physiology and diseases of the foot from the standpoint both of theory and practice. The major orthopaedic procedures connected with the treatment of severe talipes have been deliberately left out.

The book consists of twenty-six chapters; the first two dealing with the evolution and development of the foot are full of interest. It may be mentioned here that more recent work tends to emphasize the fundamental similarity in architecture of the foot of the chimpanzee and that of man. The fact that the human foot, adapted as it is for walking on the ground, bears a closer resemblance to the ape foot as used in arboreal than in terrestrial locomotion, may be regarded as satisfactory evidence of man's arboreal ancestry. It would also suggest that the essential features of man's foot were acquired at an early stage of his terrestrial existence, rather than after long apprenticeship on the ground. The author is, however, forced to the conclusion that the evolutionary destiny of the human foot is to the production of a rigid structure, having an arched form but devoid of any movements other than that at the ankle and toe joints. The tendency of the modern foot to become rigid may therefore be regarded as an evolutionary one not dependent upon the adoption of footwear.

The evolution of footwear is worthy of careful study. In both sexes, the heel should be the weight-bearing part of the foot. The anterior portion, relatively weak and degenerate, is merely intended for the preservation of balance and for assistance in the 'take off'. On the whole, modern male footwear, if not quite ideal, may be regarded at least as a happy compromise with utility and as such cannot be subjected to much serious criticism. In the female, wearing of high heels brings about effects which are in opposition to the evolutionary trend in that it throws the strain on the anterior half of the foot and so reverses the natural indication as to the destiny of the anterior and posterior limbs of the longitudinal arch. The formation and significance of the arch receives careful consideration in the chapter on flat foot and the author is inclined to the older view, *viz.*, that the arch is a static structure, depending for its maintenance, when the foot is inactive, chiefly upon the conformation of the bones and the strength of ligaments and other soft structures on the plantar aspect. But the modern school of orthopaedists holds the view that there is no such structural arch and that the observed arch in the living foot is pulled up by the postural tonus of the muscles, with the foot inactive. Sir Arthur Keith's description of the evolution of a functional arch, by the transference of muscular attachment from one part of the foot to another, appear to lend powerful support to the postural theory.

Hallux valgus has also received careful attention. The older description of this condition as a purely local deformity is abandoned in favour of the view that regards it as but a part of a much more general derangement of the foot. In the author's opinion, the most satisfactory operation is the one in which the base of the proximal phalanx is removed, while the metatarsal head, except for some slight modelling and removal of the osteophytes, is left intact. It is important to retain the articular cartilage over the phalangeal base, since the object is to produce a

movable joint. Exigencies of space prevent us from referring to the remaining chapters in detail. It may be briefly stated that other deformities of the foot, painful heels and a number of miscellaneous conditions have been adequately dealt with.

In short, it is an excellent book and although there may be some divergence of opinion on many points, it can be thoroughly recommended. We have no hesitation in saying that the author has been eminently successful in the objective with which this manual was written. But we think that the utility of the book would be considerably enhanced if in a future edition a suitable bibliography is appended. The print, illustrations and get-up are all that could be desired.

P. N. R.

THE STOMACH AND DUODENUM.—By G. B. Eusterman, M.D., F.A.C.P., D. C. Balfour, M.B., M.D. (Tor.), LL.D., F.A.C.S., F.R.A.C.S., and Members of the Staff (The Mayo Clinic and the Mayo Foundation for Medical Education and Research, Graduate School, University of Minnesota). 1935. W. B. Saunders and Company, Philadelphia and London. Pp. xv plus 958, with 436 illustrations. Price, 45s.

This comprehensive volume is the combined work of Drs. Eusterman and Balfour, and some thirteen other contributors all of whom are on the staff of either the famous Mayo Clinic itself, or the Mayo Foundation for Medical Education and Research at the University of Minnesota.

The book is made especially interesting by the fact that as Dr. Eusterman is the head of the division of medicine and Dr. Balfour is the head of the division of surgery at the Mayo Clinic, both the medical and surgical aspects of diseases of the stomach and duodenum are intimately correlated and are at the same time placed before the reader.

This is a great advantage for though many purely surgical books and many purely medical books have been written on the stomach and duodenum, they are frequently biased and the authors often dogmatic on the aspect from which they write and sceptical of the other side of the question.

In this volume, however, each pathological entity is discussed impartially from the medical and surgical outlook, and the results of each method of treatment are carefully tabulated, the experience of the authors being represented by case histories and records.

The book begins with an extremely interesting history of the recognition and treatment of gastric and duodenal diseases, first from ancient times through the Renaissance, then through the seventeenth, eighteenth and nineteenth centuries to the present day, from which it can be noted that it was probably in the first 10 years of the present century that the greatest strides in the surgical treatment of peptic ulceration were made, notably by Moynihan and the Mayo brothers.

Then follow sections on the applied physiology and the surgical pathology, after which comes a long discussion on the description and treatment of gastric and duodenal ulceration.

This section is very well done, the authors paying particular attention to medical treatment in the first place, and stressing what is the generally accepted doctrine of the present day; that it must be complete, and surgical interference should not be adopted until it is obvious that medical treatment is not going to effect a cure. They recommend however that owing to the menace of carcinoma, and greater liability to perforation when the ulcer is situated in the stomach, that medical treatment of this condition should not be persisted in for so long a time as in duodenal ulceration, unless the patient responds well to the treatment from the first.

The accomplishment of surgery in benign lesions of the stomach and duodenum is rightly described as one of the triumphs of modern medicine, and all the operations such as gastro-enterostomy alone, or with excision

of the ulcer, pyloroplasty, partial and complete gastrectomy, etc., are most carefully and completely described, each being accompanied by a symposium of its pros and cons and what particular type of case which in the author's opinion it is most suitable for.

Gastric carcinoma, hypertrophic pyloric stenosis, paraduodenal hernia and all other lesions to be found in the stomach and duodenum are fully dealt with in their turn.

In the discussion on the treatment of gastritis and hyperacidity a welcome word of warning against the uncontrolled use of sodium bicarbonate is given.

No mention anywhere in the book is made of the use of histidine in the treatment of gastric and duodenal disease.

The volume is very well got up, is beautifully printed, and contains many excellent diagrams, x-ray photographs and tables.

H. E. M.

TUMOURS OF THE URINARY BLADDER.—By E. BEER, M.D., F.A.C.S. Baillière, Tindall and Cox, London. Pp. vii plus 166, with 58 illustrations including 8 in colour. Price, 16s.

This is a neat little monograph written only on tumour formations in the urinary bladder. It is the outcome of the experience of the author on the subject for a period extending over a quarter of a century, and the result of systemic observation of numerous cases which have been studied by a specialized 'team' in the surgical unit of the Mount Sinai Hospital, N. Y., under the able leadership of Dr. Beer.

The allotment of pages to the discussion of the various items has been done very carefully and economically, and no better introduction of the subject-matter could have been made than with a historical sketch. The few pages taken up by this will be appreciated by those who are interested in the evolution of the present-day knowledge of the subject.

The incidence, symptomatology, pathology and the methods of diagnosis have all received adequate considerations in the succeeding three chapters. The last 100 pages of the book have been devoted exclusively to an elaborate discussion of the treatment by various methods, with statistics of the results thereof. An outstanding feature of the book is the exhaustive bibliography at the end. It is a somewhat strange coincidence that the experience of the author over a quarter of a century has required a bibliography covering also about a quarter of the main book, i.e., 30 pages out of a total of 130!

The paper, printing and the illustrations, specially the coloured ones, are worthy of the excellent subject-matter as well as of the rather high price of 16/-. In conclusion, we are only too glad to admit our disappointment in having been unable to find any mistake in the book—a matter which the publishers can well be proud of.

M. N. D.

TONSILS AND NASO-PHARYNGEAL SEPSIS.—By E. A. Peters, M.D. (Cantab.), F.R.C.S. (Eng.). 1935. Baillière, Tindall and Cox, London. Pp. vii plus 92. Illustrated. Price, 5s.

MR. PETERS has succeeded in producing a very valuable little book on a time-worn and threadbare subject.

In the short space of 92 pages he proves that nasopharyngeal disease and early respiratory disease are associated in providing the portal for most infections of the present day. This is of course well known if not generally admitted; but the author proves his thesis so convincingly that it would be a good thing if this little book were in the hands of all general practitioners and all doctors responsible for the health of school children.

As the author points out, tuberculous glands of the neck were very common indeed in the past, but the removal of infected tonsils in addition to improved

hygiene has reduced the numbers of sufferers from this disease to nearly vanishing point. This alone is no small achievement.

If further justification were needed it will be supplied by the observant parent who reports improved vitality, temper, breathing and diminished catarrh in his child as the result of the removal of septic tonsils and adenoids.

The author gives a lot of very useful suggestions as to treatment of various throat conditions short of operation. I have not found gargles of any use in acute conditions, such as a quinsy. Hot alkaline antiseptic lotions applied with a Higginson's syringe or from a douche can be much more useful.

As regards operative treatment he says enucleation by dissection is the operation of choice in adults. My objection to this operation is that it needs such a deep anaesthesia. This does not matter if you have the services of a highly trained anaesthetist.

All children's tonsils can be cleanly enucleated with the reversal guillotine and 99 per cent of all adults' tonsils provided one has a manual dexterity of a little over the average and a lot of practice.

I repeat, it is a valuable little book.

H. S. C.

PROBLEMS IN FILARIASIS.—By T. Bhaskara Menon, M.D. (Mad.), M.R.C.P. (Lond.), Pathologist to the Government Royapuram Hospital, Madras, and Lecturer in Pathology, Stanley Medical School, Madras. Printed by Messrs. Thompson and Co., Ltd., Madras. 1935. Pp. iii plus 67. Illustrated. Price, Re. 1

AMONG the major tropical diseases the study of filariasis has not so far received sufficient attention notwithstanding the great prevalence of this infection in this country. Nearly eight years ago Sir Frank Powell Connor, Kt., pleaded for the appointment of a commission of eminent medical men for a thorough investigation of this infection. There are still a large number of problems in filariasis which have not been solved or which are imperfectly understood, and an extensive investigation of these problems is urgently needed. For instance, the treatment of the disease is a question which deserves immediate attention as no specific drug has so far been discovered. An intensive search is necessary for this purpose and the co-operation of a number of workers may be required in this connection.

The book under review has for its object the focussing of the attention of the medical profession in India on various important problems in filariasis and is thus a welcome addition to the existing literature on the subject. The book is a collection of three lectures forming the Maharaja of Travancore Curzon lectures delivered before the University of Madras. Need for further investigations in this 'much neglected' infection is forcibly brought out in his valuable foreword to the book by Sir Frank Powell Connor, Kt., D.S.O., K.H.S., F.R.C.S., I.M.S., Surgeon-General with the Government of Madras, who writes:—'Filariasis still remains in South India, and in many other parts of the world, as a vast unsolved problem causing misery and disability to millions of human beings. This does not mean that we know little or nothing about this affection, for we know a great deal; but much more has yet to be discovered before the problem can be said to be mastered'.

In the first lecture Dr. Bhaskara Menon deals with the epidemiological problem and that of clinical types. The author points out that while the prevalence of filariasis along the coast line districts and along the banks of rivers is capable of explanation a puzzling feature has been the peculiar distribution of the infection in endemic areas. 'Small circumscribed foci are met with where the infection rate is very high, but neighbouring areas with very similar climatic conditions show only a lower incidence'. The results obtained by various investigators in this connection are summarized. The author seems to revert to the old

theory of Manson (1898)—which Manson himself discarded in his Lane lectures (1905)—that the infection is transmitted through water containing the infective larvæ. While no doubt the problem was not clearly understood till recently, systematic work carried out at the Calcutta School of Tropical Medicine has explained this peculiar distribution of the infection and it is now clear that the distribution of the infection primarily depends upon three factors, *viz.* (1) density of mosquito population, (2) density of human population, and (3) optimum conditions of temperature and humidity. It is thus possible to understand the low incidence of the infection in an area which adjoins a highly endemic centre, *e.g.*, Ernakulam and Cochin. Even in the same town the infection is not uniform. For instance, in Cuttack the microfilaria rate is very much higher in the central wards of the town than those on the outskirts. This feature is typical of *Wuchereria bancrofti* infection which is the most common parasite in India. The prevalence of filariasis in cities like Calcutta with good pipe water supply, and especially among the European population, shows definitely that the infection could not be explained as due to the use of water with infective larvæ. On the other hand a consideration of the factors mentioned above, such as density of mosquito population and density of human population, can successfully explain this peculiar distribution.

Another problem requiring explanation is the variation in clinical types met with in different localities. The author raises the question whether this difference may be due to the infective larvæ invading the skin in different areas in differing localities and states that it is difficult to imagine how the genital lesions can be caused unless we presume that the infection is water borne. If this theory is accepted it would be equally difficult to explain the presence of genital lesions among Europeans in cities like Calcutta. A more satisfactory explanation is the one offered by Acton and Rao who state that the difference in the clinical types is dependent upon the intensity of the infection in an area.

Lecture II deals with the problem of microfilarial periodicity. The explanation offered by Clayton Lane and the results obtained by various investigators are discussed in detail, as well as the objections raised against Lane's theory by Low and Manson-Bahr. The author appears to favour the theory of cyclical parturition during the day put forward by Lane, but rightly points out that further research work is necessary in this connection to support either view. The latter part of the lecture deals with pathological problems and contains a valuable summary of the investigations carried out by different workers. In this section the author gives an account of his own work and reproduces a number of photomicrographs obtained by him.

In the last lecture, Dr. Menon discusses the pathology of elephantiasis, methods of diagnosis, and treatment. A useful survey of these subjects is given. A valuable feature of this section consists in the account of the author's own researches on some of these problems, especially the radiosopic method of diagnosis. Five radiograms showing the opacities of calcified worms in elephantoid tissue, in the wall of a hydrocele sac, and in lymphangitis of the arm are given. As regards treatment, the author shows that inorganic and organic compounds of antimony, organic arsenicals and gold therapy tried so far have been disappointing and that anti-streptococcal vaccines are very popular with the profession in India. The newer method of treatment described by O'Connor of injecting sulpharsphenamine directly into the abode of the parasite has been tried with success. The difficulty with this method of treatment is the location of the worms although radiography might give a valuable clue. The lecture concludes with a forcible appeal for need for further work in filariasis.

S. S. R.

ANTENATAL AND POSTNATAL CARE.—By F. J. Browne, M.D. (Aberd.), D.Sc., F.R.C.S. (Edin.), F.C.O.G. 1935. J. and A. Churchill, Limited, London. Pp. xv plus 480, with 58 illustrations. Price, 15s.

Antenatal and Postnatal Care is a book that can be recommended with confidence to students and doctors who undertake the care, supervision and treatment of expectant mothers. Conscientious application of the practical instruction contained in the book will do much to rescue antenatal care from the disrepute into which it has fallen by being inadequately and perfunctorily practised. At the same time the book indicates gaps in our knowledge, and will, if it is studied and its lessons applied, increase the interest of the antenatal clinic by stimulating investigation and experimental treatment.

The physical ills from which the antenatal mother suffers in western countries are very fully dealt with and Dr. Grantly Dick Read has contributed an interesting chapter on the influence of the emotions upon pregnancy and parturition. One chapter is devoted to the anæmias of pregnancy, but osteomalacia and tetany receive only brief treatment, and the diarrhoeas and tropical diseases which complicate pregnancy and the puerperium in the East are not mentioned.

Only eleven out of the 430 pages of text are allotted to the organization and administration of antenatal and postnatal clinics. The omission is to some extent compensated by the inclusion as an appendix of the recommendations printed in the *Interim Report of the Departmental Committee on Maternal Mortality* on the conduct and scope of antenatal clinics. The best site for the clinic, its relationship to the midwife and public health services, these and other administrative problems are largely neglected by clinical workers, yet they merit greater attention and are of sufficient importance to warrant inclusion in future editions.

Antenatal care is a subject of growing importance; the literature is limited and Professor Browne's contribution is an important review of present knowledge and practice. The expert will find the bibliography valuable, and the book itself will have a wide sphere of usefulness amongst doctors practising obstetrics.

J. M. O.

MEDICAL RESEARCH COUNCIL. THE PATHOGENIC AEROBIC ORGANISMS OF THE ACTINOMYCETES GROUP.—By Dagny Erikson. Special Report Series No. 203. Published by His Majesty's Stationery Office, London. Pp. 61. Illustrated. Price, 1s. 6d.

'THIS report deals with a systematic study of infective micro-organisms belonging to a group which lies on the border line between the true fungi and the bacteria which multiply by fission. It is the result of work done by Miss Dagny Erikson in the National Collection of Type Cultures, maintained by the Medical Research Council at the Lister Institute, London.

Real advance in the study of fungi of medical importance has for long been hindered, as professional mycologists have often remarked, by inadequate examination and description of strains recovered from various human and animal sources, and by a confused and irresponsible nomenclature which has greatly embarrassed the archives of the subject. Accurate comparative investigation of pathogenic strains by modern methods, moreover, has been impeded through cultures described and docketed in the literature being allowed to die out. It was one of the chief objectives of the Council, in founding the National Collection in this country, to improve this state of affairs by soliciting the deposition there of inadequately identified strains which could be retained in the living state for comparative study when occasion arose'.

'For general classification Miss Erikson has found Orskov's morphological scheme most convenient, and she has succeeded in identifying by their cultural, morphological and biochemical properties no fewer than

twenty-five species, including fifteen that appear to be entirely new. Her report is fully illustrated by many plates accompanying the text, and the Bacteriology Committee of the Council have recommended its publication in the hope that it will form a useful basis for future work aimed at the analysis, on serological lines, of possible antigenic affinities between different members of this highly polymorphic and difficult group of pathogenic organisms.

A MANUAL OF PRACTICAL CHEMISTRY FOR PUBLIC HEALTH STUDENTS.—By A. W. Stewart, D.Sc., A.I.C. Third Edition. 1935. John Bale, Sons and Danielsson, Limited, London. Pp. xiv plus 121. Illustrated. Price, 7s. 6d.

This manual is designed to supply the necessary practical chemistry exercises for D.P.H. students. It is divided into parts dealing with (i) acidimetry and alkalimetry, (ii) air analysis, (iii) water analysis, (iv) analysis of foods and beverages, and (v) disinfectants and preservatives. At the end of these sections there are a few pages devoted to a summary of the more important British Ministry of Health and other reports of chemical interest. The whole text is interleaved with blank pages to enable the students to record their experiments and make necessary notes. There are several diagrams to illustrate the apparatus used and two of these illustrate some water organisms. The notes explaining the object of an experiment, the description of the process, the reactions involved and the standards in use are very concise and clear. The book is not intended to replace the standard textbooks on public health chemistry, but can be safely recommended for the use of public health students and workers in public health laboratories.

S. G.

BODY WATER: THE EXCHANGE OF FLUIDS IN MAN.—By John P. Peters, M.D. 1935. Baillière, Tindall and Cox, London. Pp. ix plus 405. Price, 18s.

DR. JOHN P. PETERS for many years has been working on the distribution and movements of solutes and water in the human body, and the present volume gives a brief summary of these investigations, as well as a review of the whole subject of fluid exchanges in the body.

The first eight chapters deal with exchange of fluid and the chemical forces which control them, the nature and movements of interstitial fluid and lymph, exchanges between blood and interstitial fluids, serous fluids and transudates, exchanges between blood cells and serum, exchanges between tissue cells and interstitial fluids, water oxidation and losses through skin and

respiratory passages, and exchanges in the gastrointestinal tract. The last four chapters deal exhaustively with the nature of renal activity and mechanism of excretion of urine. This is not surprising, as the author in the preface states that the initial stimulus for this work comes from a desire to elucidate the phenomena seen in nephritis.

The book gives a very clear and lucid exposition of a very difficult subject such as only a worker like Dr. Peters could produce; it will be welcomed by those interested in the question of fluid exchange in the body. At the end of the book there is an extensive bibliography comprising of 875 references.

R. N. C.

ACTINOTHERAPY TECHNIQUE: AN OUTLINE OF INDICATIONS AND METHODS FOR THE USE OF MODERN LIGHT THERAPY.—With Foreword by Sir Henry Gauvain, M.D., M.Chir. (Camb.), F.R.C.S. (Eng.). Third Edition. 1935. Published by the Sollux Publishing Company, Slough. Pp. 190.

This small book is published by the Sollux Publishing Company. Since its first appearance in 1933 it has been twice revised making it an annual publication.

Part I comprising fifty pages is devoted to an outline of the physical data of actinic rays, their physiological effects and the dosage.

Part II is devoted to treatment of diseases arranged alphabetically. The descriptions of appropriate treatment are very briefly given but under each disease are included references to the literature. The references which number 1,082 are given serial numbers so that needless repetition is avoided, for the reference is given in full in the first instance in which it is quoted and on subsequent occasions the number only need be given. This book will be found of use mainly as an up-to-date bibliography for practitioners employing this form of treatment rather than a textbook of the subject.

FELLOWSHIP EXAMINATION PAPERS FOR THE DIPLOMAS OF THE ROYAL COLLEGE OF SURGEONS, EDINBURGH, 1931-35. E. and S. Livingstone, Edinburgh. Pp. 44. Price, 2s. 6d. net; postage, 2d.

FELLOWSHIP examination papers are always useful and interesting to teachers of surgery and also to post-graduate students going up for higher studies. The present volume contains the examination papers of the Edinburgh fellowship for the years 1931-35. Now that an increasing number of Indian students are going up for higher qualifications in surgery, the present volume may be recommended to their notice. It is a handy little volume and the printing and get-up are excellent.

P. N. R.

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1933. VOLUME I. ON THE STATE OF THE PUBLIC HEALTH IN BRITISH INDIA AND SOME INDIAN STATES

[Continued from last issue, p. 58]

Malaria.—The relationship of the incidence of malaria with rice cultivation was alluded to in my report for 1931. Since then, the breeding of anopheles in relation to rice cultivation has been investigated in Lower Bengal by Mr. Purnendu Sen, Entomologist, Public Health Department, Bengal. In his introductory remarks Mr. Sen says:—

'There has been a tendency during recent years among certain malariologists to associate the paddy

fields in the proximity of human habitations with the malariousness of a place. That is to say, the rice fields have been considered by many as the chief source of anopheline output in a locality, the water accumulating in these fields furnishing the necessary breeding surfaces for these mosquitoes. The suspicion has naturally induced certain municipalities and other corporate bodies responsible for public health to prohibit wet cultivation within a mile or a half of their jurisdiction.'

'Rice being the staple food of this province, this prohibition might cause great distress to the people and the matter, therefore, deserves serious consideration from the public health authorities of the country. The mere presence of rice swamps might not be sufficient to indicate that the place would be malarious. As one can understand this would greatly depend on the extent to which the cultivation is found to afford

breeding facilities to those anophelines which are known to transmit malaria'.

'But unfortunately we are not fully aware what exact rôle is being played by the rice swamps under normal circumstances on the life and distribution of these carrier species of anophelines. Wide divergence of opinion on this point exists amongst different workers, some claiming their complete dissociation in the causation of malaria while others consider the rice fields as the main source of trouble'.

The investigation covered a period of two years, from October 1932 to September 1934. His important conclusions are reproduced below:—

'The intensity of anopheline breeding in the paddy fields of Bengal villages varies in different localities. It is not always that the amount of breeding in these fields is greater than the breeding of anophelines in other types of water collections in the villages'.

'The breeding in the paddy fields commences in July and ends in January following. The maximum breeding, however, takes place in September'.

'The presence of paddy fields in the vicinity of villages does not always signify that the place will be malarious, nor do the paddy fields always breed carrier species of anopheles'.

'The species noted from the different paddy fields are—*A. hyrcanus* var. *nigerrimus*, *A. barbirostris*, *A. subpictus*, *A. vagus*, *A. varuna*, *A. aconitus*, *A. ramsayi*, *A. annularis*, *A. philippinensis*, *A. pallidus* and *A. tessellatus*. Of these *A. varuna*, *A. annularis* and *A. philippinensis* have been reported to be infected in nature in Bengal'.

'The species, *A. pallidus* and *A. tessellatus*, occur only very rarely, and *A. hyrcanus* var. *nigerrimus* comprises nearly 50 per cent of the total catch'.

Quinine.—Details of the amounts of quinine and cinchona febrifuge issued in districts in each province make it clear that in no area are adequate amounts of the drug available.

Botanical survey of India.—At the close of 1933-34 the total Government of India stock of quinine sulphate purchased as such and extracted from Java and Burma barks amounted to 267,657 lbs. as against 282,759 lbs. in 1932-33.

Government cinchona plantations and factory in Bengal.—A total of 1,131,960 lbs. of bark was harvested whilst 1,659,090 lbs. were available from the previous year. Altogether 1,436,796 lbs. were utilized in the factory of which 1,268,365 lbs. belonged to the Bengal Government and the balance to the Government of India. The products obtained were 51,094 lbs. of quinine sulphate, including 3,085 lbs. in process, and 28,523 lbs. of cinchona febrifuge, the distribution according to the sources being—

	Quinine sulphate, lbs.	Cinchona febrifuge, lbs.
Munseong bark	37,309	20,508
Mungpoo "	8,419	4,621
Burma "	2,805	2,367
Java "	2,561	1,027
TOTAL	51,094	28,523

The total cost of the bark was Rs. 4.72 per lb. and that of extraction of quinine was Rs. 2.721 per lb. Thus the production of quinine has cost Government Rs. 7.441 per lb.

Madras Government cinchona department.—A total of 22,716 lbs. of quinine sulphate was produced, including quinine sulphate and tablets 20,999 lbs., quinine hydrochloride 1,348 lbs., quinine dihydrochloride 588 lbs., cinchona febrifuge 13,141 lbs. and totaquina 2,124 lbs.

Dysentery and diarrhoea.—These diseases were responsible for a higher mortality than in the previous year in Madras, Delhi, Bengal and Ajmer-Merwara. Of the total, 127,666 deaths were among males and 118,498 among females; 199,161 deaths were registered in rural and 47,003 in urban areas and the urban death

rate exceeded the rural in every province. As usual the third quarter, which corresponds with the monsoon period, recorded the highest number of deaths.

Tuberculosis.—The recorded statistics available from seven provinces show that tuberculosis is mainly an urban disease. Whilst two per cent of the recorded deaths from all causes are due to tuberculosis of the lungs, nearly 5 per cent were registered in urban and only about 1 per cent in rural areas. This however is certainly an underestimate as in Delhi municipality, for example, where registration is more accurate, the number of deaths ascribed to phthisis was found on verification to be 850 in 1933 or nearly twice the figure actually reported by the ordinary agency. In urban areas where registration is less accurate, this difference is likely to be even greater, whilst in rural areas the situation is still worse. Tuberculosis is now almost certainly one of the main public health problems in India, ranking probably next to malaria in this respect. In fact, it may be regarded as an epidemic disease. Most western countries are said to have already passed through the epidemic stage, the peak of the epidemic in England was reached as far back as 1820, but it is difficult to state exactly at what stage the disease now is in India. Some hold that the peak has not yet been reached; that India is still in the early stages; and that the extent of tuberculization of the population in India to-day is midway between that of the African races and the highly industrialized and urbanized European races. This view may or may not be correct but the fact remains that the disease is rampant. If one lays stress on the results obtained by the tuberculin test, the infection rate would seem to vary between 21 and 76 per cent according to the density of population, giving an average of 46 per cent. The bad housing conditions, the congestion and overcrowding, the unhygienic habits and customs of the people and the increasing urbanization and industrialization are without doubt conditions which predispose to rapid spread of infection, but the increasing interest in the disease, the earlier detection of cases and improved registration must be partly responsible for the increased figures. Social conditions, however, are pre-eminently suitable for spread of infection and the solution of the problem lies deep-rooted in the habits and customs of the people. No anti-tuberculosis campaign can hope to attain success if this fact is not constantly kept in mind.

The figures do not confirm the view held by some that tuberculosis presents a more serious problem in rural areas than in the towns. Whilst it is probable that tuberculosis infection is more common in the ordinary village than available statistics would indicate, anyone acquainted with rural life in India knows that, although sanitation is primitive and housing is of a low standard, men, women and children all live an active outdoor life and do not suffer from the overcrowding and ill-ventilation which is so common a feature in Indian cities and towns. These facts alone would go to indicate that tuberculosis infections cannot be anything like as ubiquitous in the rural areas as they are in the towns and there seems little reason to think otherwise. No doubt, the industrial workers of the cities are drawn from the village populations and those workers who fall victims to tuberculosis return to their villages when they find themselves no longer able to work, so that in certain areas from which industrial recruits are drawn there may be considerable numbers of active tuberculosis cases but this applies to very small parts of rural India and can have on the whole little influence on the tuberculosis rate in the general rural population of the country.

Notification of disease is an essential preliminary to any constructive measures for prevention and treatment and it is regrettable that little or no progress can be reported in this respect. In England and Wales as far back as 1907 the Local Government Board encouraged the voluntary notification of cases of pulmonary tuberculosis; in 1912 it was made compulsory. The position in India is one of marked contrast to

of the hot weather, *i.e.*, in the months of March, April and May.

Even modern medicine seems to be able to do little for the prevention and treatment of this serious disease. The Government of India Central Research Institute at Kasauli has prepared and issued an anti-meningococcic vaccine manufactured from cultures originally taken from cases in Delhi and this product is now under trial in selected communities, such as jails, schools and other institutions of the kind. Similar efforts have been made by the Director of the Haffkine Institute, Bombay, who has isolated strains of the meningococcus from cases at Ahmedabad. It is not so far possible to indicate the results obtained with these vaccines, and although the experts of the Ministry of Health in England are inclined to think that they may be of value, it is still premature to hazard any definite opinion.

Anti-meningococcic serum has not hitherto been manufactured in India, but English supplies have been imported and stocked for the needs of the Army and for civil purposes on emergency indents. The preparation of anti-meningococcic serum in India will depend largely on the results of the tests now under experiment, but it is proposed to make the attempt as soon as the 'type' question has been settled. This seems more than desirable because the results which have so far been obtained in India with English serum have not been entirely satisfactory.

[This abstract will be concluded in our next issue.]

REPORT ON THE SESSION OF THE OFFICE
INTERNATIONAL D'HYGIENE PUBLIQUE
HELD IN PARIS, 29TH APRIL TO 8TH MAY,
1935. BY LIEUT.-COL. G. G. JOLLY, C.I.E.,
V.H.S., M.B., D.P.H., D.T.M., I.M.S., DEPUTY
DIRECTOR-GENERAL, INDIAN MEDICAL
SERVICE, DELEGATE FOR THE GOVERN-
MENT OF INDIA

INFORMATION ON YELLOW FEVER RECEIVED DURING THE
SIX MONTHS ENDING 31ST MARCH, 1935

Notified cases of yellow fever.—During the last quarter of 1934 and the first quarter of 1935, Africa, Brazil and Columbia were only countries from which notifications of cases and deaths from yellow fever were received by the Office International d'Hygiene Publique.

Protection test results.—During the period under review the mouse-protection test has fully maintained its reputation as a reliable method of ascertaining the occurrence of yellow fever in the past. Some interesting results have been obtained by the application of the test in places which used to suffer frequently from epidemics but have been free from clinical cases for 20 or more years. For example the blood of 12 out of 16 Cubans who were born before 1901 (which was the year of the last great yellow fever epidemic in that island) contained protective immune bodies while no person among 14 who were born after 1908 (which year the disease had been completely eradicated) possessed any immunity. The same complete absence of immune bodies in the blood of persons aged 20 years and under was found as a result of examining the blood of 72 persons born in the island of Barbados. The test has also been of great assistance in investigations at Guayaquil and elsewhere in deciding whether patients whose illness was provisionally diagnosed as yellow fever had really suffered from this disease or not. The fact that the blood of these persons after recovery from the illness contained no yellow fever immune bodies, and that the results of protection tests made on a large number of children in neighbouring localities were uniformly negative, indicated that probably Guayaquil and other ports on the Pacific coast of America are free from yellow fever at the present time. In this connection an important pronouncement made by Dr. Soper at the Ninth Pan-American Sanitary Conference recently held at Buenos

Aires was that during the last five years yellow fever in epidemic form has not been present in any important port on the American continent, nor has any evidence of the international spread of yellow fever virus been obtained.

The application of 'viscerotomy'.—Viscerotomy is the operation by which, without making an autopsy and without mutilating the body, a specimen of liver tissue for histo-pathological study is extracted through a hole from 1 to 2 centimetres wide, made with a viscerotome in the costal area of the hepatic region. The operation is very quickly performed and, on withdrawing the cannula of the instrument, the hole in the skin closes of itself without it being necessary to join the edges with a stitch or to apply adhesive plaster.

The practice of viscerotomy has not yet been adopted widely in Africa but viscerotomes have recently been sent to Bathurst (Gambia), Freetown (Sierra Leone), Accra (Gold Coast) and to the Anglo-Egyptian Sudan, Kenya and Uganda. In other parts of Africa viscerotomy has not yet been practised, but in some areas, in French Equatorial Africa, partial autopsies are made in certain fatal cases and the specimens of liver tissue obtained at these autopsies are sent to the Pasteur Institute, Paris, for examination.

Vaccination against yellow fever.—In England the method of immunization against yellow fever by the inoculation of neurotropic virus and yellow fever immune serum is being continued. The number immunized in London by this method now amounts to 424. As a rule the yellow fever immune serum used is the heterologous serum of Pettit and Stefanopoulos in doses of 0.4 to 0.5 c.c.m. per kilogramme of body-weight, but for persons who are found (by a preliminary intradermal inoculation of 0.1 c.c.m. of the serum) to be highly serum-sensitive, human yellow fever immune serum is used. The chief disadvantage of the use of the heterologous serum is that occasionally severe urticaria and arthritis follow the inoculation. In addition to the protective inoculations done in England on persons proceeding to Africa and South America, 158 Europeans were immunized by the same method at Bathurst, Kerewan, Kuntaur, Georgetown and Basse in the Gambia during or shortly after the recent outbreak of yellow fever in that colony. During this outbreak the Laigret method of immunization, in which immune serum is not used, was also applied to some extent in Bathurst, and it is understood that practically every European resident in the Gambia can now be regarded as having been immunized against the disease. The result is very satisfactory because the Gambia is a colony in which natural conditions and other factors make it very difficult to take effective anti-mosquito and other measures for reducing permanently the endemicity of yellow fever and preventing its spread.

NOTE ON YELLOW FEVER INVESTIGATIONS IN THE
ANGLO-EGYPTIAN SUDAN

Routine histological examinations of livers from all suspected cases have been carried out and although no cases of yellow fever have been diagnosed clinically since last June any sections considered in the least suspicious were submitted to Dr. Findlay for his opinion.

Of seven sections sent he reported five as not yellow fever and two were considered suspicious. One case was from a western immigrant in Wad Medani with a clinical history of jaundice, seven days' fever, coma, death. The other section was also from a western immigrant—a cattle man—admitted moribund to El Obeid hospital with deep jaundice and fever. Some areas of the liver were suspicious but in the absence of clinical details and examination of other organs it was 'not possible to be certain'.

Of the two cases the one from Wad Medani gave a negative protection test while it was impossible to obtain serum from the other.

Only one case was considered even clinically suspicious by the local medical authorities. This was from

that in England. So far there is no Ministry of Health as such; there is no Central Board of Health; and there is no general Public Health Act under which tuberculosis and other regulations might be framed.

Since public health and disease prevention are 'transferred' subjects, no one general policy is followed in India in regard to the prevention of tuberculosis. The Public Health Commissioner with the Government of India has neither direct nor indirect control and the different provinces plan independently where they plan at all. The only All-India Organization solely concerned with anti-tuberculosis work in India is the King George's Thanksgiving (anti-tuberculosis) Fund. This organization is ill-equipped financially and for this reason confines its activities mainly to propaganda work. The provincial municipal and other Acts do not include provisions for anti-tuberculosis work and will have to be amended before they can be made applicable; the position as regards rural areas is even worse.

Beri-beri.—The figures do not give any accurate estimation of the true incidence of the disease in the general population, but even so they once more differentiate clearly the main rice-growing provinces from those where rice is not the staple article of diet.

[Epidemic dropsy and beri-beri do not appear to be differentiated in this report, as the former disease is not mentioned.]

Ankylostomiasis.—Much the highest number was as usual recorded in the Madras Presidency.

Leprosy.—The high rates recorded in Madras are a measure of the anti-leprosy campaign's activities in this province.

Kala-azar.—In the concluding paragraphs of a paper by Drs. L. E. Napier and K. V. Krishnan the position is summarized in these words:—

'It is thus apparent that in Madras the disease is truly endemic and not subject to much variation from year to year; in Assam it is epidemic and disappears almost entirely from many places in the inter-epidemic period; in Bengal the state of affairs is intermediate between these two extremes, it is endemic, more or less throughout the province, but is subject to periodic increases of incidence. Or to refer to the disease of a population as one would the disease of an individual—in Madras it is chronic, in Bengal sub-acute with periodic exacerbations, and in Assam it is acute with periodic relapses'.

'When the disease is invading virgin soil, the mass immunity is low, the infection is easily established, and the disease is epidemic; the clinical disease—the evidence of the fight between the parasite and host—is acute, there is little scope for host-parasite adjustment, and the result is a decisive victory on one side or the other. This was the state of affairs in the early Assam epidemics; history relates that 95 per cent of patients died, the rest being completely cured. Amongst so small a number of surviving hosts, there would be a negligible number, if any, of examples of imperfect immunity response'.

'With an increase in mass immunity in the population, which inevitably follows the subjection of a population to repeated epidemics, the disease will become endemic, it will assume a less acute symptomatology—the host-parasite battle will be less severe; there will be more scope for host-parasite adjustment, there will be a greater number of surviving hosts, and the examples of imperfect immunity response will begin to appear. This is the state of affairs that existed in Bengal up to about 15 years ago'.

'With the further increase in mass immunity the chronic forms of the visceral disease appear, there are still more survivors and amongst these a greater number show evidence of imperfect immunity response, i.e., dermal lesions; this is the state of affairs which we believe exists in some rural endemic areas in Southern India to-day'.

'Our conclusion is that in Southern India are the oldest foci of kala-azar as far as India is concerned, that here the disease has passed through the two stages

now seen to exist in Assam and Bengal, respectively, and has reached a "chronic" stage where there is no rise and fall in incidence from year to year and the disease is truly endemic, and that the transmission is almost entirely from dermal infections, so that treatment of kala-azar cases alone does not affect the general incidence of the disease'.

Relapsing fever.—True relapsing fever is not common in India. It has been pointed out that the large numbers recorded in Bengal are not true relapsing fever; most of the so-called cases are probably due to malaria or other fevers in which relapses are a common feature. In an attempt to correct this error in registration it has been suggested to provincial public health departments that the word 'spirochætal' should be inserted after the word 'relapsing fever'. It remains to be seen if this will be sufficient to indicate to medical officers and others that relapsing fever is a definite disease.

Cerebro-spinal meningitis.—In a public health memorandum issued in 1932, the gradual spread of epidemic cerebro-spinal meningitis to the East was discussed and all available information as to the incidence of the disease in India was given in a series of tables. In 1932 figures showed that although cerebro-spinal meningitis had occurred in sporadic fashion in a number of towns and districts, there was little evidence that it existed anywhere in epidemic form.

An examination of available records, however, indicates that cerebro-spinal meningitis has certainly been known in India for over half a century.

The most notable epidemics in recent times have been that of 1931 in the Shikarpur special jail in Sind (Bombay Presidency); that of 1932-33 in the Lahore Borstal Institution, Punjab; the 1933-34 epidemic in Ahmedabad town in the Bombay Presidency; and that of 1933-34 in Delhi city. In the first of these, the infection appears to have been introduced from Upper Sind, a so-called endemic area. Despite precautions, sporadic cases occurred between April and December 1931, and the mortality was high, as 12 of the 13 recorded cases died. During 1932, 7 further cases with 4 deaths occurred, these being evidence of the difficulty of freeing an institution of infection once it is introduced.

Other outbreaks occurred during 1932, but except for that in Calcutta, no accurate figures can be quoted. In Nagpur, in the Central Provinces, for instance, 5 cases with 3 deaths were recorded. In Burma, a total of 14 deaths were registered in seven different urban areas, so that in this province infection seems to have been fairly widespread. In Calcutta, the cases numbered 145 and deaths 143. It is probable that in this city many cases remained undetected, as a cent per cent mortality rate is unusual, but there is little doubt that Calcutta was the centre of a serious outbreak.

During 1933, 142 cases with 68 deaths were recorded in Delhi city. Several of these cases were imported from outlying districts from which it is clear that by this time infection was widespread in rural areas. In the neighbouring city of New Delhi, also, 12 cases with 6 deaths were recorded, whilst in the Delhi jail 4 cases and 3 deaths occurred in 4 different gangs of prisoners.

Another sharp outbreak occurred in the Motihari jail in Bihar and Orissa during April 1933. Within three weeks, 11 cases with 6 deaths were recorded but after further 4 cases in May the infection disappeared.

During the whole of 1933, the disease continued in the city of Calcutta and no fewer than 387 cases and 348 deaths were recorded. Isolated cases were also reported from a few other places such as Chittagong and Baranaghat towns. In the Punjab, whilst no further outbreaks occurred in the Borstal Institution, a number of sporadic cases were recorded in Lahore city.

As regards periodicity, generally speaking, the incidence gradually increases to its peak at the beginning

of the hot weather, *i.e.*, in the months of March, April and May.

Even modern medicine seems to be able to do little for the prevention and treatment of this serious disease. The Government of India Central Research Institute at Kasauli has prepared and issued an anti-meningococcic vaccine manufactured from cultures originally taken from cases in Delhi and this product is now under trial in selected communities, such as jails, schools and other institutions of the kind. Similar efforts have been made by the Director of the Haffkine Institute, Bombay, who has isolated strains of the meningococcus from cases at Ahmedabad. It is not so far possible to indicate the results obtained with these vaccines, and although the experts of the Ministry of Health in England are inclined to think that they may be of value, it is still premature to hazard any definite opinion.

Anti-meningococcic serum has not hitherto been manufactured in India, but English supplies have been imported and stocked for the needs of the Army and for civil purposes on emergency indents. The preparation of anti-meningococcic serum in India will depend largely on the results of the tests now under experiment, but it is proposed to make the attempt as soon as the 'type' question has been settled. This seems more than desirable because the results which have so far been obtained in India with English serum have not been entirely satisfactory.

REPORT ON THE SESSION OF THE OFFICE INTERNATIONAL D'HYGIENE PUBLIQUE HELD IN PARIS, 29TH APRIL TO 8TH MAY, 1935, BY LIEUT.-COL. G. G. JOLLY, C.I.E., V.H.S., M.B., D.P.H., D.T.M., I.M.S., DEPUTY DIRECTOR-GENERAL, INDIAN MEDICAL SERVICE, DELEGATE FOR THE GOVERNMENT OF INDIA

INFORMATION ON YELLOW FEVER RECEIVED DURING THE SIX MONTHS ENDING 31ST MARCH, 1935

Notified cases of yellow fever.—During the last quarter of 1934 and the first quarter of 1935, Africa, Brazil and Columbia were only countries from which notifications of cases and deaths from yellow fever were received by the Office International d'Hygiene Publique.

Protection test results.—During the period under review the mouse-protection test has fully maintained its reputation as a reliable method of ascertaining the occurrence of yellow fever in the past. Some interesting results have been obtained by the application of the test in places which used to suffer frequently from epidemics but have been free from clinical cases for 20 or more years. For example the blood of 12 out of 16 Cubans who were born before 1901 (which was the year of the last great yellow fever epidemic in that island) contained protective immune bodies while no person among 14 who were born after 1908 (which year the disease had been completely eradicated) possessed any immunity. The same complete absence of immune bodies in the blood of persons aged 20 years and under was found as a result of examining the blood of 72 persons born in the island of Barbados. The test has also been of great assistance in investigations at Guayaquil and elsewhere in deciding whether patients whose illness was provisionally diagnosed as yellow fever had really suffered from this disease or not. The fact that the blood of these persons after recovery from the illness contained no yellow fever immune bodies, and that the results of protection tests made on a large number of children in neighbouring localities were uniformly negative, indicated that probably Guayaquil and other ports on the Pacific coast of America are free from yellow fever at the present time. In this connection an important pronouncement made by Dr. Soper at the Ninth Pan-American Sanitary Conference recently held at Buenos

Aires was that during the last five years yellow fever in epidemic form has not been present in any important port on the American continent, nor has any evidence of the international spread of yellow fever virus been obtained.

The application of 'viscerotomy'.—Viscerotomy is the operation by which, without making an autopsy and without mutilating the body, a specimen of liver tissue for histo-pathological study is extracted through a hole from 1 to 2 centimetres wide, made with a viscerotome in the costal area of the hepatic region. The operation is very quickly performed and, on withdrawing the cannula of the instrument, the hole in the skin closes of itself without it being necessary to join the edges with a stitch or to apply adhesive plaster.

The practice of viscerotomy has not yet been adopted widely in Africa but viscerotomies have recently been sent to Bathurst (Gambia), Freetown (Sierra Leone), Accra (Gold Coast) and to the Anglo-Egyptian Sudan, Kenya and Uganda. In other parts of Africa viscerotomy has not yet been practised, but in some areas, in French Equatorial Africa, partial autopsies are made in certain fatal cases and the specimens of liver tissue obtained at these autopsies are sent to the Pasteur Institute, Paris, for examination.

Vaccination against yellow fever.—In England the method of immunization against yellow fever by the inoculation of neurotropic virus and yellow fever immune serum is being continued. The number immunized in London by this method now amounts to 424. As a rule the yellow fever immune serum used is the heterologous serum of Pettit and Stefanopoulo in doses of 0.4 to 0.5 c.c.m. per kilogramme of body-weight, but for persons who are found (by a preliminary intradermal inoculation of 0.1 c.c.m. of the serum) to be highly serum-sensitive, human yellow fever immune serum is used. The chief disadvantage of the use of the heterologous serum is that occasionally severe urticaria and arthritis follow the inoculation. In addition to the protective inoculations done in England on persons proceeding to Africa and South America, 158 Europeans were immunized by the same method at Bathurst, Kerewan, Kuntaur, Georgetown and Basse in the Gambia during or shortly after the recent outbreak of yellow fever in that colony. During this outbreak the Laigret method of immunization, in which immune serum is not used, was also applied to some extent in Bathurst, and it is understood that practically every European resident in the Gambia can now be regarded as having been immunized against the disease. The result is very satisfactory because the Gambia is a colony in which natural conditions and other factors make it very difficult to take effective anti-mosquito and other measures for reducing permanently the endemicity of yellow fever and preventing its spread.

NOTE ON YELLOW FEVER INVESTIGATIONS IN THE ANGLO-EGYPTIAN SUDAN

Routine histological examinations of livers from all suspected cases have been carried out and a number of cases of yellow fever have been identified since last June any sections considered in the least suspicious were submitted to Dr. Findlay for his opinion.

Of seven sections sent he reported five as not yellow fever and two were considered suspicious. One case was from a western immigrant in Wad Medani with a clinical history of jaundice, seven days' fever, coma, death. The other section was also from a western immigrant—a cattle man—admitted moribund to El Obeid hospital with deep jaundice and fever. Some areas of the liver were suspicious but in the absence of clinical details and examination of other organs it was 'not possible to be certain'.

Of the two cases the one from Wad Medani gave a negative protection test while it was impossible to obtain serum from the other.

Only one case was considered even clinically suspicious by the local medical authorities. This was from

Rumbek in the Bahr-El-Ghazal Province and showed deep jaundice, black vomit and melæna. There was, however, no fever during the 48 hours in hospital before death and there was a leucocytosis of 50,000. The liver section was negative.

Nine out of 43 sera from cases of jaundice gave positive protection tests, of these 8 were from districts in the Southern Sudan where the previous survey gave positive protection tests and the ninth was the immigrant from Wad Medani mentioned above. These results confirm the geographical distribution of the positive protection tests as shown by Dr. Hewer's survey.

Dr. de Vogel read a long and interesting paper giving the results of his historical investigations into the experience of a Sudanese battalion which was sent to Mexico in 1863 because its men were considered immune to yellow fever. He draws various deductions and in the course of the paper discusses the danger of the spread of the disease to India and the East. Because of certain provocative remarks, the paper was not well received, but it is a valuable contribution which might be worth translating.

LIEUT.-COL. JOLLY'S STATEMENT AT THE YELLOW FEVER COMMISSION

I have been much interested in Dr. de Vogel's paper because he has expressed in it a point of view which has not perhaps yet received the attention it deserves—the point of view of the countries now threatened with an invasion of yellow fever, either through an infected mosquito or an infective person.

The danger appears to us to draw nearer every day. With the establishment of the new air line from West Africa to Khartoum which it is proposed to inaugurate this year, India will be brought within one week of West Africa. The danger of infection of India by sea may not at the moment be so acute but it exists and once East Africa becomes infected, and this appears to us to be only a matter of time, it will become immediate.

We are not satisfied with the exclusion of the so-called silent areas from the provisions of the convention. We are not convinced that these silent areas do not contain active foci of the disease.

I have been impressed by Dr. Morgan's account of the viscerotome service in Brazil. It appears to be not only the newest but also the simplest and most economical method of locating the disease and of following its fluctuations from day to day. Until by the establishment of a viscerotome service the silent areas have been made to speak, they must remain under grave suspicion, and air traffic should be protected within their limits in the same manner as is prescribed for proved infected areas.

India's alarm at the danger of the introduction of yellow fever from Africa does not confine itself merely to a desire to see all reasonable steps taken at countries of export. She has carried out *Aedes* surveys in Rangoon and Bombay and has begun mosquito control in both these ports. She is also taking steps to render her main air-port of entry at Karachi mosquito-free.

I have here a copy of a resolution passed by the Twelfth Annual Conference of Research Workers of India which met at Calcutta in November 1934 and which while it does not carry the authority of the Government of India expresses the considered opinion of a large and representative body of medical men engaged in research and public health work in India. With your permission I shall read this resolution.

RESOLUTION NO. 15, PASSED BY THE TWELFTH CONFERENCE OF MEDICAL RESEARCH WORKERS, HELD AT CALCUTTA BETWEEN THE 26TH NOVEMBER AND 1ST DECEMBER, 1934

In light of the recent developments in connection with yellow fever in Africa including the occurrence of suspected cases of the disease in areas where positive mouse-protection tests had been obtained although no clinical cases had previously been recognized, this conference views with concern the opinion expressed by

the Yellow Fever Commission of the Office International at its May 1934 session that the establishment of anti-amaryl aerodromes and the application of the other requirements of Section II of the Aerial Sanitary Convention are not obligatory in regions where the only information available is that of positive mouse-protection tests.

In the absence of exact knowledge of the epidemiological significance of the so-called 'silent areas' and the potentialities which these areas may possess for the dissemination of yellow fever, this conference considers that the approval given by the Yellow Fever Commission of the Office International to the exemption of such areas from the application of the provisions of Article 38, Chapter II of the Aerial Sanitary Convention, entails a weakening of the chain of preventive measures. This conference further expresses the opinion that such areas should be considered as definite yellow fever areas for the purpose of the application of the provisions of the convention and that the full requirements of the Aerial Sanitary Convention (Chapter II, Section II) should be made immediately applicable to them.

This conference is of opinion that the Government of India should take drastic precautions against air traffic coming from the 'silent areas' where the administrative authorities of these areas have not established anti-amaryl aerodromes.

[We have only abstracted portions of this report which refer to yellow fever, especially in connection with the danger to India, but many interesting discussions also took place on other major epidemic diseases most of which are of interest to medical authorities in India. We are however unable to include these in this abstract on account of want of space.]

ANNUAL REPORT ON THE WORKING OF THE RANCHI INDIAN MENTAL HOSPITAL, KANKE, IN BIHAR AND ORISSA, FOR THE YEAR 1934

DURING the year under report the Ranchi Indian Mental Hospital continued to receive patients from the provinces of Bengal and Bihar and Orissa, as in the previous years.

The accommodation of the hospital remained the same, viz, 1,014 for males, 272 for females, total 1,286. The 50 emergency beds sanctioned by Government in 1929 to relieve overcrowding in the male section were in demand throughout the year. There was no overcrowding in the female section.

As reported in previous years, none of the expansion projects could be taken up during the year under review, owing to continued financial difficulties.

In theory the advantage of treatment in the early and hopeful stage is not disputed. It seems that we shall never be able to see early cases in this hospital for treatment in large numbers until such time as the public is sufficiently educated as to the advantages of early treatment in modern mental hospitals. No matter how much we may deplore it, a strong odium is still attached to mental disease, and the relations desire to keep secret the fact that anyone in their family is so affected. The problem of encouraging early treatment cannot be solved without securing the confidence of the patient and of his family and any measure which will conduce to this end is worthy of careful consideration. It will not be out of place to report below the words of His Majesty the King-Emperor, when opening the Shenley Mental Hospital in England on 31st May, 1934: 'I note with satisfaction that, in designing this hospital, you have paid special regard to the treatment of the mental illness in its early stages by the addition of a Reception Hospital which I look forward to seeing to-day'.

The death rate of this, the largest, has again been the lowest of all the mental hospitals of India.

The general health of patients has been good throughout the year under report; there has been no outbreak of any epidemic disease during the year.

The insanitary area within the male enclosure, referred to in my last annual report, has since been reclaimed at a cost of Rs. 1,180, and I have every reason to believe that the heavy incidence of malaria in the male enclosure will now be generally lessened.

Although a considerable amount of freedom was enjoyed by the patients I am happy to be able to record that there was no case of escape during the year under report.

Sulphur injections in mental disorders.—Eighty patients were given this treatment during the year with the following results:—

Stationary or no improvement.	Improved	Recovered
29	35	16

Hitherto we have tried this most useful therapy in 295 cases with the following gratifying results:—

Stationary or no improvement.	Improved	Recovered
114	120	51

The above table shows that we have effected 17.3 per cent recovery and 40.7 per cent improvement in our patients by this method and we feel more happy over these results as we were the first in India to experiment with sulphur injections.

[Other forms of modern treatment in mental disease were employed in appropriate cases and it is clear that the hospital is quite up to date. Occupational therapy and amusements also continue to play a large part in the conduct of this hospital.]

Correspondence

NON-PLAGUE RAT MORTALITY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—As far as I am aware, it is generally thought that when rats die, daily, in great numbers, they are only plague-infected ones. This view is held, not only by the lay public, but also by several medical men.

In view of this idea, the following is interesting:—In February last, plague occurred in a village, 5 miles from Ratnagiri, with a number of attacks and some deaths. Some of the villagers seemed to have come into this town from this plague-infected village and, soon after, there began to be here a rat mortality, of about 8 to 10 rats a day. It was therefore presumed that the infection was brought from this village. A rat was sent to me for examination by the municipality. On examination, I found, it had enlarged glands in the neck and other post-mortem appearances indicative of its being a plague-infected one. A smear from the spleen showed, microscopically, several plague bacilli. I, therefore, declared it a plague-infected one. A few days after, some rats were sent to the Parel Laboratory and the report was that they were not plague-infected.

Rats continued to die for nearly a month, but no case of plague occurred. Subsequent to the first examination, I examined other rats and found them not to be those of plague. There were no enlarged glands and no other signs indicative of plague. I was sure, however, that the first one was plague-infected.

I now recount what happened the previous year in 1934. Rats began to die every day and my predecessor, I understand, declared them to be plague-infected. Some way or other, it was not credited by the public that they were plague-infected. This want of belief was fostered, presumably, by the following incident at Chiplun, a taluka of this district, a short time previously. At this place, rats were falling for about 2 months and were declared by the Parel Laboratory, not to be plague-infected. No case of plague occurred at Chiplun. In Ratnagiri, however, plague broke out very severely, with 92 attacks and 61 deaths and created greater havoc, inasmuch as the town had not been evacuated when the rats were falling and no inoculations done until later. I understand that the first report from Parel about rats sent there was negative and positive for those sent a second time. The number of inoculations done were 11,000, with no death amongst the inoculated. The following questions and ideas arise, which may be considered:—

1. Whether this disease, which seems harmless to man, can be transmitted from one rat to the other and thus make it an easy problem for rat destruction.

2. Whether this disease simultaneously, starts amongst rats, when plague is commencing among them,

but, before the latter can get a hold among them, the other wipes them off.

3. It may be mentioned that rats dying from this disease, die similarly to those of plague. They seem intoxicated and die towards places where water is stored.—Yours, etc.,

J. F. HENRIQUES, L.M. & S.,
F.C.P. & S., B.M.S.,
Civil Surgeon.

RATNAGIRI,

TRAINING IN PHARMACY IN INDIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—With great pleasure I read the speech recently delivered by Colonel Chopra in the Rotary Club, Calcutta.

I intend to say a few words in this connection. All-Bengal-Compounders Association was changed into 'Bengal Pharmaceutical Association' in 1934 under the presidency of Colonel Chopra whose object is to build up the profession of pharmacy on a scientific and ethical basis, and to protect the public from the grave danger to which it is constantly exposed due to the scandalous way in which the drug trade is carried on in the country. In all other civilized countries in the world, the drug trade and the profession are controlled by laws. But unfortunately in India, the profession of pharmacy is practically ignored and the compounders who represent the profession are in a horrible condition. No systematic training is given to them throughout the whole country and above all there is total absence of laws to control their qualification. The training imparted to them is so very inadequate that they become wholly unequal to discharging their responsible duties. In other countries their professional brethren are thoroughly conversant with the science of pharmacy and are only engaged for their particular work, but in India the compounders are not only employed for dispensing medicines but they also have to perform the duties of dressers, operation assistants, anaesthetists, nurses, etc. The chaotic condition of the compounders, who are even unjustifiably designated as compounders instead of pharmacists, or chemists and druggists, is fully discussed in the Report of the Drugs Enquiry Committee (1930-31) which calls for stringent measures to cope with it urgently. The Bengal Pharmaceutical Association drew the attention of the authorities concerned towards the miserable plight of compounders on account of the defective training and the result was that the State Medical Faculty of Bengal appointed a sub-committee to revise their syllabus. Colonel Chopra, I.M.S., was its Chairman. The committee finished

their task and submitted their report along with a thorough and comprehensive syllabus properly drawn up by them at the meeting of the Governing Body of the said Faculty held on the 17th February, 1934. It was approved of and unanimously passed in the said meeting. The committee strongly recommended it for an early introduction. It is a matter of great surprise that about two years have elapsed and it is still lying unapproved of by the Government of Bengal. We do not know the fate of it. I dare say if the new curriculum be introduced, the development of pharmaceutical industry will be considerably helped by the newly-trained compounders (pharmacists). Without well-trained personnel the serious situation created by the adulterated drugs cannot be improved.

Under these circumstances I, with all emphasis, draw the special attention of the Government of Bengal for the introduction of the new syllabus at any rate by the next session for the training of the compounders (pharmacists), as a preliminary action for the prevention of sale of spurious drugs and as an essential part of the legislation proposed. I also urge both the provincial and Central Governments to give effect to the recommendations of the Drugs Enquiry Committee as early as possible which are so vital to the well-being of the country and its people.—Yours, etc.,

KARUNA KUMAR ACHARJEE,
Member, Bengal Pharmaceutical
Association, Standing Committee.

POST KUNDULIA, HOWRAH,
23rd November, 1935.

UNUSUAL IDENTIFICATION OF EXPLOSIVE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the September issue, 1935, of your esteemed journal it has been mentioned, on page 506, by Dr. N. J. Vazifdar, that after a bomb explosion 'arsenic' enters into the system through the wound and also by inhalation of arsenuretted hydrogen which is evolved in the explosion.

A bomb of the type under discussion explodes due to the interaction of sulphide of arsenic with an oxidizing agent such as 'potassium chlorate' and there is no likelihood, under the circumstances, of any trace of arsenuretted hydrogen being formed.

It is not arsenuretted hydrogen, but 'oxide of arsenic' in gaseous state or in solid state of very fine subdivision, which is formed as a result of explosion, enters into the system.—Yours, etc.,

T. C. BASU CHOWDHARY.

AGRA,
1st January, 1936.

THE TREATMENT OF LOBAR PNEUMONIA WITH INTRAVENOUS INJECTIONS OF ALCOHOL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I have read the article 'The Treatment of Lobar Pneumonia with Intravenous Injection of Alcohol' written by Captain Ilahi Bakhsh, I.M.S., and Captain A. T. Andreasen, I.M.S. I wish to treat cases of pneumonia according to their opinion, but confusion arises in my mind. The writers advise to inject a solution of 20 per cent alcohol in sterile normal saline. I wish to know what sort of alcohol, whether absolute alcohol or a liquor which contains 20 per cent alcohol?

Also I wish to know if I use 'Vini Gallici No. 1' how much proportion shall I add in 20 c.cm., because 'Vini Gallici No. 1' contains only 47 to 57 per cent of alcohol?

Yours, etc.,

SOURENDRA NATH MITTRA, L.M.F.

INDAS (BANKURA),
3rd January, 1936.

The above letter was forwarded to Captain Andreasen who has sent us the following information:—

[Note.—'The alcohol used is rectified spirit. The strength used is:—33½ per cent rectified spirit in normal (sterile) saline. The dose is 20 to 25 c.cm. of this mixture. We have recently found that adding sufficient sterile sodium bicarbonate solution (gr. xx to ㉟i) to this mixture to render it just alkaline seems to eliminate the rigors which sometimes follow the injection. This addition of sodium bicarbonate is not always necessary because the mixture may be already neutral or alkaline'.—EDITOR, I. M. G.]

JHIN-JHINIA AND ITS CURE

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I am a subscriber of your journal with the hope of getting some experience in it. Though I have got no special privilege to bring forward before you in medical points of view—I cannot help but writing a few lines:—

It is my earnest request I shall be very much obliged if you kindly pay a little attention to the following:—

In some parts of Bengal many people are suddenly attacked with a kind of disease which seems to me to be 'Neuro-Toxæmia' called Chin-chinia (ঝিন-ঝিনিয়া) in Bengali. It is found that some patients are getting attacked with pneumonia due to constant pouring of water and applying ice-bag on the head. Again it is very often found in our Mofussil, patients are lying dead in the open-field and path for want of water and company.

It is a matter of regret no remedy is yet out for the convenience of the public.

On investigation I have practically used an internal medicine on more than 100 patients without applying water and ice-bag on head and the people in our locality are getting a charming benefit thereby.

In any stage of the patient when the medicine taken internally the great prominent symptoms such as unconsciousness, severe throbbing of the limbs and burning sensation of the higher centres will be off in 2 to 5 minutes and the patient will be relieved perfectly within half an hour.

I hope if you kindly take a little interest for this medicine it would be great service to the public for which I may send some samples for trial if you kindly permit.

Yours, etc.,
B. P. M.,
Medical Practitioner.

HOWRAH DISTRICT,
20th January, 1936.

[Note.—We reproduce this letter exactly as it was received except that we have replaced the full name by initials only and have deleted the address. We have made these modifications in view of the fact that our correspondent has omitted, possibly inadvertently, to mention the name or nature of the charm-affecting drug. Those who have read our editorial comments on this disease will possibly be interested in this letter. We might mention, however, that we cannot divulge either the name or address of our correspondent, B. P. M.—EDITOR, I. M. G.]

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL SIR FRANK P. CONNOR, *Kt.*, D.S.O., K.H.S., Surgeon-General with the Government of Madras, is appointed to officiate as Director-General, Indian Medical Service, with effect from the 29th October, 1935 (afternoon), *vice* Major-General C. A. Sprawson, granted leave.

Lieutenant-Colonel A. J. H. Russell, C.B.E., V.H.S., is appointed Honorary Surgeon to the King, and is promoted Brevet-Colonel, 12th August, 1935, *vice* Colonel C. A. Gill, retired.

Lieutenant-Colonel R. N. Chopra, C.I.E., is appointed Honorary Physician to the King and is promoted Brevet-Colonel, 19th August, 1935, *vice* Major-General Sir Robert McCarrison, C.I.E., retired.

The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff—

To be Honorary Surgeon

Lieutenant-Colonel J. Taylor, D.S.O., *vice* Lieutenant-Colonel A. J. H. Russell, C.B.E., V.H.S., vacated. Dated 30th October, 1935.

Lieutenant-Colonel W. M. Will is appointed Assistant Director-General, Indian Medical Service (Stores), with effect from the 28th October, 1935.

Lieutenant-Colonel J. Rodger, M.C., Residency Surgeon and Chief Medical Officer in Baluchistan, is appointed to officiate as Civil Surgeon, Quetta, in addition to his own duties, with effect from the forenoon of the 30th October, 1935, and until further orders.

The services of the undermentioned officers of the Indian Medical Service are placed permanently at the disposal of the Government of Burma, with effect from the dates mentioned against the name of each officer:—

1. Lieutenant-Colonel R. H. Malone. Dated 26th January, 1934.

2. Major G. M. Moffat. Dated 1st March, 1934.

3. Major G. M. Irvine. Dated 8th April, 1935.

Major M. P. Atkinson, an Agency Surgeon, on return from leave, is posted as Agency Surgeon, Gilgit, with effect from the afternoon of the 4th October, 1935.

The services of Major [Name] are replaced at the disposal of the [Name] Provinces, with effect from the afternoon of 25th October, 1935.

The services of Captain H. S. Waters are replaced at the disposal of the Government of Bombay, with effect from the 28th October, 1935.

Captain B. Chaudhuri, Senior Medical Officer, Andaman and Nicobar Islands, is appointed as Superintendent, Cellular Jail, Port Blair, in addition to his own duties, with effect from the afternoon of the 30th October, 1935, until further orders, *vice* Major L. H. M. Upshon, V.D., granted leave preparatory to retirement.

The following appointments are made:—

To be Lieutenants

Dated 23rd September, 1935

Rajmal Kasliwal.
Muhammad Abu Nasar Moezuddin, B.Sc. (Luck.).

Dated 30th September, 1935

Tahil D. Chablani.

Dated 2nd October, 1935

Satyanarayana Sunkavally.

Dated 7th October, 1935

Ramaswami Duraiswami Ayyar.

Dated 10th October, 1935

Addanki Seshgiri Rao.

Ram Lal Soota.

Dated 11th October, 1935

Moti Lal Shankhla, B.Sc. (Bom.).

Dated 22nd October, 1935

Drishnier Subramania Aiyer.

LEAVE

Major-General C. A. Sprawson, C.I.E., K.H.F., Director-General, Indian Medical Service, is granted leave on average pay for 2 months and 7 days combined with leave on half average pay for 1 month and 24 days, with effect from the 29th October, 1935 (afternoon).

Brevet-Colonel A. J. H. Russell, C.B.E., K.H.S., Public Health Commissioner with the Government of India, is granted leave for 8 months, with effect from the 8th September, 1935.

Lieutenant-Colonel P. Banerji, Civil Surgeon, is allowed leave for 4 months, with effect from the 22nd November, 1935.

Lieutenant-Colonel S. R. Prall, Superintendent, St. George's Hospital, Bombay, is granted leave on average pay for 6 months and 25 days, with effect from the 21st March, 1936.

Major L. K. Ledger, an Agency Surgeon, is granted leave on average pay for 4 months and 14 days combined with leave on half average pay for 4 months and 16 days, with effect from the afternoon of the 4th October, 1935.

PROMOTIONS

Colonel to be Major-General

A. W. M. Harvey, K.H.S. Dated the 14th November, 1935.

Lieutenant-Colonels to be Colonels

S. S. S. Houghton, O.B.E. Dated the 24th November, 1935, with seniority 1st March, 1930.

P. S. Mills. Dated 21st August, 1935, with seniority 1st August, 1929.

D. C. V. FitzGerald, M.C. Dated 22nd October, 1935, with seniority 1st February, 1930.

Notes

THE HISTIDINE TREATMENT

'Hypolom' histidine hydrochloride, a product of Burroughs Wellcome and Company, Snow Hill Buildings, London, E.C. 1, is a sterile, 4 per cent solution of histidine hydrochloride, ready for immediate use in cases of gastric and duodenal ulcers. The accumulated evidence of many cases shows a favourable response to this seemingly rational method of

treatment. Histidine, alone, and without dietary restrictions, has been shown to be effective in cases of ulcers of the mild type, gain in weight and improved nutrition being particularly evident. The treatment consists of daily intramuscular or subcutaneous injections for three weeks, of 5 c.cm. of a 4 per cent solution of histidine hydrochloride. No other medication is necessary, and a minimum, if any, of dietary

restrictions. 'Hypoloid' brand histidine hydrochloride 4 per cent in 5 c.cm. is supplied in boxes of 5 'Hypoloid' ampoules.

THE BLOODLESS PHLEBOTOMIST

WE have just received a copy of *The Bloodless Phlebotomist*, Vol. VIII, No. 3, which is being mailed to every physician in India.

This little journal published by the Denver Chemical Manufacturing Company of New York is replete with interesting articles written by physicians who are located in many different countries and while the purpose of the publication is to acquaint its medical readers with antiphlogistine, the physicians will find a number of items and illustrations which will excite their curiosity and interest—altogether, the little journal is well worth reading and we note that 1,450,500 copies are printed in nine languages and distributed to every doctor in the world with a known address, excepting in the countries of Russia, Latvia and Bulgaria.

If you do not receive a copy write to the Denver Chemical Manufacturing Company, New York, who will place your name on their list. The journal will be supplied you free of all charges.

HORLICK'S INDIAN CALENDAR FOR 1936

WE have received a copy of the 1936 wall calendar which is being widely distributed in India by the Horlick's Malted Milk Company, Ltd.

This firm's calendars are always conspicuous for their interest. The present one is no exception, though in subject-matter it represents a departure from the calendars issued in the past, which have generally illustrated famous scenes or subjects from the mythology or history of India.

The 1936 calendar carries an illustration of the impressive and colourful scene in St. Paul's Cathedral, the heart of the Empire, during the Thanksgiving Service held there on the occasion of the Silver Jubilee of the King-Emperor. There are two smaller illustrations, one of Their Majesties driving in state to the Cathedral, and the other showing them kneeling in prayer.

CEROCOL

COLLOIDAL CERIUM OXALATE

IN 1854 Sir James Y. Simpson discovered the sedative and tonic action of cerium oxalate. At the same time, he also recognized its special value in the prevention of vomiting in pregnancy and introduced it into medicine in this direction.

Cerium oxalate is an almost insoluble salt (its solubility in water is 1-8175). After oral administration it is found unchanged in the faeces. It is therefore presumed that the salt is incapable of being absorbed by the mucous membranes and its action must be regarded as mechanical, similar to that of bismuth.

Although the majority of authors agree as to the beneficial effect of cerium oxalate, its action so far has not been exactly determined.

Cerocol is a colloid-soluble form of cerium oxalate which is readily absorbed, consequently a uniform action in the prevention of vomiting of all kinds is attained.

Cerocol tablets contain 0.05 gram colloidal cerium oxalate.

Advantages.—The recently discovered colloid-soluble form of Cerocol represents a decided advantage over cerium oxalate as previously prescribed. Even those patients who usually experience a difficulty in swallowing tablets find no difficulty with Cerocol.

The tablets are small and disintegrate immediately upon the tongue. They cannot give rise to irritation with resulting vomiting.

The tablets are tasteless.

They contain no narcotics nor alkaloids, and cause no after effects, such as dryness of the throat, nor any of those other unpleasant symptoms which frequently accompany the administrations of belladonna, scopolamine, hyoscyamin, etc.

The tablets are non-poisonous, even multiple doses are harmless.

Dosage.—Emesis and hyperemesis 2 tablets before rising. In severe cases a further 2 tablets during the day.

FAMOUS COMPANY HONOURED

HORLICK'S MALTED MILK COMPANY LIMITED announce that they have been honoured by His Majesty the King-Emperor with a Royal Warrant of appointment. Horlick's Malted Milk has been famous in India for over a half a century as an ideal diet for infants and invalids. It was provided to His Majesty's Forces during the Great War and has played a conspicuous part in many famous expeditions and record-breaking achievements.

Horlick's Malted Milk Company Limited is one of the few great English private companies still owned and directed by members of the founding family.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE ÆTIOLOGY OF BLACKWATER FEVER

By K. V. KRISHNAN, M.B.B.S., M.R.C.P., D.B., D.Sc.

Professor of Malariology and Rural Hygiene
and

N. G. PAI, M.A.

(The All-India Institute of Hygiene and Public Health,
Calcutta)

Introduction

THE ætiology of blackwater fever is one of the unsolved puzzles in tropical medicine. Although several investigators have studied the various problems connected with it (Thompson, 1924, and Ross, 1932) the factors concerned in the causation of this condition are, even now, not clearly understood. One of the chief difficulties in the way of progress has been the lack of suitable and sufficient experimental material. The recent discovery by Napier and Campbell (1932) of a monkey plasmodium (*P. knowlesi*) capable of producing hæmoglobinuria in susceptible species has to some extent overcome this difficulty and given a fresh impetus to the study of the problems connected with hæmolysis and hæmoglobinuria. The work on monkeys that is being conducted at present will, it is hoped, not only throw light on the factors involved in hæmolysis and hæmoglobinuria in these animals but also indicate the mode of production of blackwater fever in man. In this article, therefore, an attempt is made to present the various questions relating to the ætiology of blackwater fever that are awaiting an answer and to discuss them in the light of results obtained in recent researches on monkeys by us in the belief that the underlying factors in hæmoglobinuria of monkeys are fundamentally the same as those in blackwater fever in man.

Is blackwater fever a disease per se or a manifestation of malaria?

The isolation of a spirochæte (*S. biliohæmoglobinuria*) by Blanchard and Lefrou (1922) and a few others, from a certain number of blackwater fever cases, gave rise to the suggestion that this organism may be the ætiological agent of the disease. But the failure of Blacklock, Leger, Thompson (1924), Ross (1932) and several others to find the organism in the blood or urine of blackwater fever cases, even after repeated examinations, indicated that the disease was not of spirochætal origin.

The consensus of opinion at present is that it is a manifestation or complication of malaria and this opinion is based on the following observed facts:—Blackwater fever generally occurs in certain hyperendemic malarial areas; it does not occur in non-malarious areas nor in

areas where epidemic or low-endemic malaria prevails. If and when blackwater fever cases occur in non-malarious localities, the patients invariably give a history of previous residence in hyperendemic malarious areas. While blackwater fever is rare among the indigenous inhabitants of hyperendemic areas it is frequently met with among the susceptible immigrant population. Such of the immigrant population that suffer most from malaria are also those that develop blackwater fever. It is only after repeated attacks of malaria that blackwater fever results—primary infections being rarely accompanied by hæmoglobinuria and a residence of at least 6 months to 4 years being necessary before the blackwater condition develops. The incidence of blackwater fever cases is most common in the malarial season or shortly after it and there is also a close correlation between the number of malarial cases and the number of blackwater fever cases in the endemic areas.

In 75 to 90 per cent of blackwater fever cases malarial parasites can be demonstrated in the blood either a few days before the onset or a few days after the disappearance of hæmoglobinuria. The majority of the cases show malignant tertian parasites, but in a few cases benign tertian and quartan parasites have also been seen. Post-mortem findings in blackwater fever cases are enlarged spleen, pigment, parasites, and other evidence of malaria. Whenever malaria control is properly effected, blackwater fever disappears from the locality.

These findings not only establish that malaria is an essential condition precedent to blackwater fever but they also indicate that the predisposition to blackwater fever induced by malaria may be due either to a specially virulent strain of the malarial parasite prevalent in the endemic areas, or to a lowering of host resistance to blackwater fever through repeated attacks of malaria or to both.

Is blackwater fever due to a specially virulent strain of the malarial parasite?

Nocht (1931), Giglioli (1932) and others have suggested that blackwater fever may be related to a particular 'strain' or 'biological variety' of the malarial parasite. This strain is supposed to be highly virulent, capable of producing a hæmolytic toxin and inducing blackwater fever. Their assumption is based on some observed facts such as the peculiar geographical distribution of blackwater fever, its absence from certain hyperendemic areas, and its reputed familial and house incidence in some localities. But unless some one actually isolates the hæmolytic strain, describes its differential characteristics, isolates the toxin produced by it, and proves its hæmolytic character and its ætiological rôle in blackwater fever, this theory will not be considered proven. Furthermore, the theory fails to explain many known facts relating to blackwater fever. For

restrictions. 'Hypoloid' brand histidine hydrochloride 4 per cent in 5 c.cm. is supplied in boxes of 5 'Hypoloid' ampoules.

Introduction

THE ætiology of blackwater fever is one of the unsolved puzzles in tropical medicine. Although several investigators have studied the various problems connected with it (Thompson, 1924, and Ross, 1932) the factors concerned in the causation of this condition are, even now, not clearly understood. One of the chief difficulties in the way of progress has been the lack of suitable and sufficient experimental material. The recent discovery by Napier and Campbell (1932) of a monkey plasmodium (*P. knowlesi*) capable of producing hæmoglobinuria in susceptible species has to some extent overcome this difficulty and given a fresh impetus to the study of the problems connected with hæmolysis and hæmoglobinuria. The work on monkeys that is being conducted at present will, it is hoped, not only throw light on the factors involved in hæmolysis and hæmoglobinuria in these animals but also indicate the mode of production of blackwater fever in man. In this article, therefore, an attempt is made to present the various questions relating to the ætiology of blackwater fever that are awaiting an answer and to discuss them in the light of results obtained in recent researches on monkeys by us in the belief that the underlying factors in hæmoglobinuria of monkeys are fundamentally the same as those in blackwater fever in man.

Is blackwater fever a disease per se or a manifestation of malaria?

The isolation of a spirochæte (*S. biliohæmoglobinuria*) by Blanchard and Lefrou (1922) and a few others, from a certain number of blackwater fever cases, gave rise to the suggestion that this organism may be the ætiological agent of the disease. But the failure of Blacklock, Leger, Thompson (1924), Ross (1932) and several others to find the organism in the blood or urine of blackwater fever cases, even after repeated examinations, indicated that the disease was not of spirochætal origin.

The consensus of opinion at present is that it is a manifestation or complication of malaria and this opinion is based on the following observed facts:—Blackwater fever generally occurs in certain hyperendemic malarial areas; it does not occur in non-malarious areas nor in

areas where epidemic or low-endemic malaria prevails. If and when blackwater fever cases occur in non-malarious localities, the patients invariably give a history of previous residence in hyperendemic malarious areas. While blackwater fever is rare among the indigenous inhabitants of hyperendemic areas it is frequently met with among the susceptible immigrant population. Such of the immigrant population that suffer most from malaria are also those that develop blackwater fever. It is only after repeated attacks of malaria that blackwater fever results—primary infections being rarely accompanied by hæmoglobinuria and a residence of at least 6 months to 4 years being necessary before the blackwater condition develops. The incidence of blackwater fever cases is most common in the malarial season or shortly after it and there is also a close correlation between the number of malarial cases and the number of blackwater fever cases in the endemic areas.

In 75 to 90 per cent of blackwater fever cases malarial parasites can be demonstrated in the blood either a few days before the onset or a few days after the disappearance of hæmoglobinuria. The majority of the cases show malignant tertian parasites, but in a few cases benign tertian and quartan parasites have also been seen. Post-mortem findings in blackwater fever cases are enlarged spleen, pigment, parasites, and other evidence of malaria. Whenever malaria control is properly effected, blackwater fever disappears from the locality.

These findings not only establish that malaria is an essential condition precedent to blackwater fever but they also indicate that the predisposition to blackwater fever induced by malaria may be due either to a specially virulent strain of the malarial parasite prevalent in the endemic areas, or to a lowering of host resistance to blackwater fever through repeated attacks of malaria or to both.

Is blackwater fever due to a specially virulent strain of the malarial parasite?

Nocht (1931), Giglioli (1932) and others have suggested that blackwater fever may be related to a particular 'strain' or 'biological variety' of the malarial parasite. This strain is supposed to be highly virulent, capable of producing a hæmolytic toxin and inducing blackwater fever. Their assumption is based on some observed facts such as the peculiar geographical distribution of blackwater fever, its absence from certain hyperendemic areas, and its reputed familial and house incidence in some localities. But unless some one actually isolates the hæmolytic strain, describes its differential characteristics, isolates the toxin produced by it, and proves its hæmolytic character and its ætiological rôle in blackwater fever, this theory will not be considered proven. Furthermore, the theory fails to explain many known facts relating to blackwater fever. For

example why a long residence in a blackwater area is a preliminary to the onset of the condition, why first attacks of malaria caused by the hæmolytic strain do not result in blackwater fever, and why only persons most susceptible to malaria generally fall victims to the disease, are not explained by it. Taking an impartial view of the question, however, it seems that a 'biological strain' of the malarial parasite (meaning by the term not necessarily a toxin-producing strain but a strain differing in some other respect, such as biochemical activity, pathogenicity, etc.) is most probably concerned. But even this assumption of a special strain will not in itself be sufficient to explain all known facts relating to blackwater fever. The factor of host response to malarial infection appears to us to be of far greater importance than the parasite factor. Unless the host factor is taken into account it seems that an accurate and complete picture of blackwater fever will be difficult to obtain.

Is the nature of host response to malaria an important factor in the causation of blackwater fever?

That repeated attacks of severe malaria and increased susceptibility of the individual to malaria play an important part in the ætiology of blackwater fever is established by epidemiological findings. The higher incidence of the condition in susceptible immigrants residing in certain hyperendemic malarial areas, and in people who had previously been attacked with severe malaria, supports this view. This assumption also explains why a certain period of residence in blackwater areas is necessary before the predisposition to the disease is acquired. Confirmatory experimental proof of this theory has recently been obtained in monkeys infected with *P. knowlesi*. It has been shown that hæmoglobinuria ordinarily occurs as a complication of malaria only in the susceptible *rhesus* monkeys and not in the relatively more resistant *irus* and *radiatus* monkeys (Napier and Campbell, 1932). Even in the susceptible *rhesus* monkeys dying of intense infection all do not develop the condition (Krishnan, 1935). It is in only those in which the infection develops rapidly and intensely that hæmoglobinuria is met with (Krishnan, Smith and Lal, 1933). By lowering the resistance of *irus* and *radiatus* monkeys, which do not suffer from hæmoglobinuria ordinarily, by splenectomy, we have shown (Krishnan, Smith and Lal, 1933) that hæmoglobinuria can be induced in some of them. All these suggest that, in the monkey and perhaps also in man, the host factor is of greater importance than the parasite factor.

The recent work on the mechanism of resistance to malaria and hæmoglobinuria has shown that some of the factors involved are common to both. For example, the functional efficiency of the reticulo-endothelial system has been

shown to be of importance in the overcoming of both the malarial infection and the hæmoglobinuric state. Therefore the nature of the host response to the initial malarial infection, it may be presumed, would greatly determine whether the host is likely to acquire an immunity or a predisposition to hæmoglobinuria. If the host acquires resistance to malaria, he would also develop immunity to hæmoglobinuria, but on the other hand if no such resistance is acquired by the host he would run the risk of developing hæmoglobinuria and every subsequent attack of malaria would greatly increase the chances of its onset. Such a view would be fully justified if we picture infection merely as a stimulus to the acquirement of immunity. As a stimulus is equally capable of acting either as an excitant or a depressant, depending upon the prevailing condition, it is conceivable how repeated attacks of malaria would in some depress the immunity response and produce conditions favourable for the onset of hæmoglobinuria, and do the opposite in others. If this view is accepted then the question of real importance to be considered in connection with the ætiology of blackwater fever is—What changes in the host induced by malaria lead to a predisposition to blackwater fever?

What changes in the host induced by malaria lead to a predisposition to blackwater fever?

The changes induced by malaria in a host which result in a predisposition to blackwater fever are not all very well understood. There are, however, a number of theories with regard to them and they may be considered under two main heads—cytological and biochemical. The former refers to changes in the reticulo-endothelial cells, the red cells, etc., and the latter to alterations in certain constituents in the blood such as cholesterol, glucose, phosphorus, bicarbonate, acids, etc. It is probable that more than one change is induced by malaria and these are concerned in bringing about a predisposition to blackwater fever. It is possible that these changes are more closely inter-related with one another than they appear at first sight.

(a) *Damage and dysfunction of the reticulo-endothelial system.*—It is well known that one of the important functions of the reticulo-endothelial system is phagocytosis and clearance of foreign particulate matter from the blood. In the course of malaria large quantities of debris are liberated into the blood at each sporulation in the form of red cell stroma, hæmoglobin, parasites and pigment and they have all to be cleared by the cells of the reticulo-endothelial system. It is possible, therefore, that repeated attacks of severe malaria might tax this system in some individuals to such an extent as to cause certain changes of a temporary or permanent nature in its proliferative and functional capacities as well as in its powers of mobilization. When such a change characterized by a damage and dysfunction of the system

has been established, conditions would not only be favourable for hæmolysis but also for the onset of hæmoglobinuria. Under these circumstances, an agent which ordinarily is incapable of bringing about hæmolysis would not only induce it, but would also lead to hæmoglobinuria, because the mechanism for clearance of hæmoglobin is defective and this substance is likely to accumulate beyond the threshold level of the kidney and get excreted in the urine. If the reticulo-endothelial system is able to respond to this final stimulus of a massive dose of hæmoglobin, hæmoglobinuria would cease and the host would recover; if not, the hæmoglobinuria would persist and end in the death of the host.

This theory is supported by convincing experimental evidence. A study of the histological changes in the spleen, which is an important store-house for reticulo-endothelial cells, shows that in hæmoglobinuric monkeys the evidence of proliferation and mobilization of these cells so characteristic of the non-hæmoglobinuric resistant monkeys is entirely absent. A similar picture of a failure of response of the reticulo-endothelial cells is also seen in the peripheral blood of hæmoglobinuric monkeys (Krishnan, Lal and Napier, 1933). In these animals prior to the onset of hæmoglobinuria, not only does the number of reticulo-endothelial cells get fewer but their functional capacity, as tested by their ability to ingest neutral red, is also diminished (Krishnan, 1935).

Furthermore splenectomy experiments have fully corroborated this view and shown that the removal of the organ results in an increase of susceptibility to malaria and hæmoglobinuria (Krishnan, 1935). Even in the resistant species of monkeys (*irus* and *radiatus*), which ordinarily do not show hæmoglobinuria, splenectomy followed by infection with *Plasmodium knowlesi* results in hæmoglobinuria in a fairly high percentage of cases (Krishnan, Smith and Lal, 1933). Hæmoglobinæmia, which has been observed to be a precursor of hæmoglobinuria in man and in monkeys, lends further indirect support to this theory; for had the reticulo-endothelial system been able to perform its functions properly hæmoglobinæmia would not have occurred, except perhaps as a very transient condition.

From these it appears that the damage to the reticulo-endothelial system that is induced by malaria in certain very highly susceptible people is undoubtedly an important factor in the ætiology of blackwater fever. It should, however, be pointed out that while this theory explains why hæmoglobinuria occurs in some and is prevented in others it fails to indicate how hæmolysis is actually caused. The questions as to whether there is a hæmolytic agent concerned and if so what is its nature are not answered by this theory.

(b) *Alteration in red cells.*—This theory suggests that repeated attacks of malaria bring

about some alteration in the quality of the red cells which renders them more liable to hæmolysis than normal cells. Whether this alteration is merely a variation in the physical properties of the cells or in their chemical constitution it is difficult to say. Any experiment undertaken to test the nature or significance of cell alterations in hæmolysis must necessarily be planned after a careful consideration of the agents and mechanism involved in hæmolysis. Lack of knowledge regarding these factors has stood in the way of devising suitable experiments.

It is well known that hæmolysis is brought about by a variety of factors, varying from the simple physical phenomenon of osmosis to the more complicated processes due to the specific action of chemical agents. The criteria involved in each of these would be widely different as also the significance of the different alterations in the cells. In the belief that hæmolysis is caused by osmotic changes, many investigators tried to demonstrate that the red cells from normal individuals differed from those obtained from blackwater fever cases in their ability to withstand the action of hypotonic saline solution. As these results were not uniform it led another group of investigators to study the question from the chemical point of view. The inhibitory action of cholesterol on hæmolysis brought about by certain agents like saponin has been known for a long time (Leathes and Raper, 1925). It was thought that a study of the variation in this constituent would not only indicate the mode of action of the hæmolytic agent, but would also show the nature of the cell alteration, if any occurred. Krishnan and Pai (1936) showed that in monkeys there is a marked diminution in cholesterol in the pre-hæmoglobinuric state and that hæmoglobinuria did not develop in the animals in which free cholesterol was normal or above normal. This suggested that the agent causing hæmolysis is one which is favoured by hypocholesterinæmia and inhibited by hypercholesterinæmia. In the case of monkeys, although Krishnan and Pai have not actually shown that the lowering of free cholesterol noted by them is due to a depletion of this constituent from the red cells, yet the evidence adduced by them indicates that such an assumption is justifiable. From this it follows that if it could be shown that the cholesterol of the red cells is altered in cases of blackwater fever in man then such a change would be an important factor in determining the extent of hæmolysis and hæmoglobinuria.

(c) *Cholesterol changes.*—Cholesterol is an important constituent of cells, cell membranes and plasma and is recognized to have an inhibitory effect on hæmolysis caused by agents such as fatty acids, and saponin. In the belief that in blackwater fever a hæmolytic agent of the saponin type may be involved, a large number of workers (Ross, Whitmore, Nocht, etc.) have studied the total cholesterol changes in this

condition. The results, although not uniform, indicated that hypocholesterinaemia preceded the onset of blackwater fever in a certain percentage of cases. Krishnan, Ghosh and Bose (1936) obtained similar results in cases of hæmoglobinuria in monkeys. The study of cholesterol changes by Krishnan and Pai (1936) with special reference to the two forms in which it is known to be present (free and ester) gave more conclusive results. These workers have shown that in the pre-hæmoglobinuric state there is a distinct lowering of free cholesterol and an increase in ester cholesterol in all cases studied. There was also a definite indication of a mobilization of free cholesterol in those cases that failed to develop hæmoglobinuria. From these observations the conclusion was drawn that free cholesterol was important as regards inhibition of hæmolysis and the hæmolytic agent is one which exerts its activity in the absence of a sufficient amount of free cholesterol. This incidentally explained the variable nature of results obtained in man with reference to total cholesterol and emphasized the necessity for a study of free and ester cholesterol separately in blackwater fever cases.

It has been observed by many that repeated attacks of malaria have a tendency to lower blood cholesterol (Krishnan, Ghosh and Bose, 1936). But there is a difference as regards the ability to mobilize cholesterol in those who have developed an immunity to malaria and those who have developed a predisposition to blackwater. While the former respond with an increase of cholesterol as a result of the stimulus of infection or treatment, the latter show a further fall in cholesterol. It seems therefore likely that one of the ways in which malaria predisposes to blackwater is by depleting free cholesterol either from the medium or the cells or both and by damaging the cholesterologenetic centres. This in our opinion appears to be a very important factor in the predisposition to blackwater fever.

(d) *Alterations in glucose.*—The importance of glucose for the growth and development of hæmo-protozoa, both *in vivo* and *in vitro*, has been demonstrated by several workers. So far as the malarial parasite is concerned the work of Hegner and MacDougall (1926) and of Bass and Johns (1913) fully justifies this view. The observation made by some other workers that glucose changes in the blood of malarial subjects have not indicated any distinct or significant alteration in every case studied (Rudolf and Marsh, 1927) cannot be interpreted as lessening in any way the importance of glucose as an essential factor in the growth of the malarial parasite. For we believe that the concentration of glucose in the blood will vary not only according to the intensity of the malarial infection but also according to the ability of the host to mobilize glucose in the blood.

This view is partly corroborated by the results of Otero (1932), and Tschilow and Mladenow (1934). The fact that in all intense infections in monkeys (Krishnan and Pai, 1936) a marked lowering of glucose invariably occurred suggests that under suitable experimental conditions it can be shown that a stage will be reached when the animal will be unable to mobilize the necessary glucose in the blood. This inability to mobilize glucose may be followed by, or be the result of, an upset in the carbohydrate metabolism. That such an upset does occur is indicated by the observation that an increase in the inorganic phosphorus of the blood is associated with the depletion in glucose, and the injection of glucose and insulin decreases the inorganic phosphorus. This altered metabolism of carbohydrates probably leads to the development of the hæmolytic agent and to a predisposition to hæmolysis and hæmoglobinuria. If this is so in monkeys, then it is conceivable how in some men, as a result of repeated attacks of malaria, the capacity of the body to utilize glucose in the normal way may be seriously altered, temporarily or permanently, and thus lead to a predisposition to blackwater fever.

The mere study of the glucose changes in the blood of blackwater fever cases may not indicate the extent of damage to carbohydrate metabolism and this may be the reason why such studies so far have not given any clue regarding any upset of the carbohydrate metabolism in man. That an upset of this metabolism does occur in man, as in the monkey, in the pre-hæmoglobinuric state is highly probable from other evidence as well. We believe that it is essential to consider this factor as being of far-reaching importance both in the ætiology and in the treatment of blackwater fever.

(e) *Alteration in inorganic phosphorus.*—The variations in inorganic phosphorus occurring in blackwater fever in man have been studied by a few investigators (Matko, 1918; Whitmore, 1928; Ross, 1932). Whitmore noticed an increase in this constituent but Ross obtained variable results. Matko advanced the view that alterations in phosphorus metabolism were responsible for hæmolysis, while Ross came to the conclusion that upsetting of the phosphorus metabolism was 'neither a preliminary to nor responsible for the intravascular hæmolysis'. The study of the alteration in this constituent in malarial hæmoglobinuria of monkeys (Krishnan and Pai, 1936) showed that there was a distinct tendency for the inorganic phosphorus to rise in the pre-hæmoglobinuric state in both splenectomized and non-splenectomized animals. In non-splenectomized monkeys not developing hæmoglobinuria, no such rise was noticed. This rise has been partly accounted for by these workers as being due to the rapid utilization of sugar through the hexose-phosphates of the corpuscles, and to the derangement of the carbohydrate metabolism. Their view appears to be

substantiated by the fact that diminution in inorganic phosphorus occurs in these cases as a result of the injection of glucose and insulin. From this it seems that the rise in inorganic phosphorus, if it occurs in blackwater fever, can not only be interpreted as being due to nitrogenous retention as shown by Ross (1932) but also as indicating a derangement in carbohydrate metabolism which appears to be an essential condition for the production of the hæmolytic agent. An absence of a rise in inorganic phosphorus does not necessarily indicate the contrary. Inorganic phosphorus may or may not be concerned directly with hæmolysis, but it does indicate the nature of the processes at work and the possible source and nature of the hæmolytic agent.

(f) *Alterations in organic phosphorus as lecithin.*—We are not aware of any work on the variations in organic phosphorus as lecithin in malaria or blackwater fever. The work of Krishnan and Pai (1936) in malarial hæmoglobinuria of monkeys shows that there is a marked increase in organic phosphorus in the pre-hæmoglobinuric state, that the increase is less pronounced in those not developing hæmoglobinuria, and least in those recovering from intense infection. This finding taken in conjunction with the rise in ester cholesterol observed (*vide supra*) suggests that as a result of intense malarial infection fatty acids are being produced and are accumulating and that one method of their disposal is by the formation of lecithin. It is difficult to say what part this rise in lecithin plays in hæmolysis. It seems that the alteration in the ratio between lecithin and free cholesterol is of some importance. When the ratio is high, conditions seem to favour the onset of hæmolysis and when it is normal or low hæmolysis is inhibited. It is also possible that the presence of lecithin in high concentration may lead directly or indirectly to the formation of hæmolysin. It would be interesting to study the variations in organic phosphorus as lecithin in human cases of blackwater fever, and until it is done it will not be possible to state whether in man there is a similar increase or not, whether it is brought about in a similar manner and whether it has a similar rôle to play. We believe that alterations in lecithin do play a part, directly or indirectly, in the hæmolytic process.

Is there a hæmolytic agent involved and if so what is its nature?

Hæmolysis of red cells may be due to a simple physical phenomenon like osmosis or to more complicated processes due to chemical agents. It is almost impossible to associate the hæmolysis leading to hæmoglobinuria in blackwater fever in man to merely physical phenomena. Although no one has been able to demonstrate the presence of a hæmolysin the assumption

that a hæmolysin is involved seems to be indispensable. If so, the three types of hæmolysins that have been suggested by different workers from time to time may be considered here:— (i) a auto-hæmolysin; (ii) a toxin of the malarial parasite; (iii) hæmolysins such as fatty acids arising out of an alteration in metabolism.

(a) *Auto-hæmolysin.*—Thompson (1924) observed some peculiar forms of red cells in malignant tertian malaria, and suggested that these may be antigenically different from normal cells and may give rise to hæmolytic antibodies. He believed that in blackwater fever cases these altered red cells were present in large numbers and that when the specific antibody was formed hæmolysis occurred. Normally, the body does not produce antibodies to its own red cells; it does so only if foreign red cells are introduced. Therefore, unless it can be shown that the abnormal red cells seen in blackwater fever cases are antigenically different from normal red cells, that they can induce the formation of antibodies, and that these antibodies are hæmolytic, this hypothesis cannot be accepted. Furthermore, the hæmolysin detected by a few workers in the sera obtained from some of the blackwater fever cases has not been shown to be of the nature of an auto-hæmolysin.

(b) *Toxin of malarial parasite.*—This hypothesis has already been discussed to some extent in the section on the 'biological strain' of the malarial parasite. Here it needs only to be emphasized that a 'biological strain' meaning a strain which is particularly capable of inducing pronounced metabolic changes and leading to the formation of hæmolytic substances in the body of the host is probably concerned. Such an assumption seems to be justified because that alone helps to explain the total absence of blackwater fever in certain hyperendemic malarial areas and the reputed house and familial distribution of cases in some localities. In view of the evidence presented in the other sections in this paper suggesting that profound alterations in the glucose and fat metabolisms in conjunction with a damaged state of the liver are the predisposing factors to hæmolysis the assumption of an exotoxin of the parasite seems to be unnecessary. Furthermore, no one has isolated it or described its qualities, and the onus of proof of this rests with those who make the assumption.

(c) *Hæmolysins such as fatty acids arising out of an alteration in metabolism.*—Several observers have found in chronic malaria evidence of an upset of the acid base equilibrium and a lowering of the bicarbonate reserve. This suggests that in the course of malaria there is overproduction of acid and that possibly this reaches a stage in some persons when hæmolysis can be readily caused. Blacklock and Macdonald (1928) have strongly supported this view and have incriminated lactic acid as a possible agent. The work of Ross (1932), however, shows that

condition. The results, although not uniform, indicated that hypocholesterinæmia preceded the onset of blackwater fever in a certain percentage of cases. Krishnan, Ghosh and Bose (1936) obtained similar results in cases of hæmoglobinuria in monkeys. The study of cholesterol changes by Krishnan and Pai (1936) with special reference to the two forms in which it is known to be present (free and ester) gave more conclusive results. These workers have shown that in the pre-hæmoglobinuric state there is a distinct lowering of free cholesterol and an increase in ester cholesterol in all cases studied. There was also a definite indication of a mobilization of free cholesterol in those cases that failed to develop hæmoglobinuria. From these observations the conclusion was drawn that free cholesterol was important as regards inhibition of hæmolysis and the hæmolytic agent is one which exerts its activity in the absence of a sufficient amount of free cholesterol. This incidentally explained the variable nature of results obtained in man with reference to total cholesterol and emphasized the necessity for a study of free and ester cholesterol separately in blackwater fever cases.

It has been observed by many that repeated attacks of malaria have a tendency to lower blood cholesterol (Krishnan, Ghosh and Bose, 1936). But there is a difference as regards the ability to mobilize cholesterol in those who have developed an immunity to malaria and those who have developed a predisposition to blackwater. While the former respond with an increase of cholesterol as a result of the stimulus of infection or treatment, the latter show a further fall in cholesterol. It seems therefore likely that one of the ways in which malaria predisposes to blackwater is by depleting free cholesterol either from the medium or the cells or both and by damaging the cholesterologenetic centres. This in our opinion appears to be a very important factor in the predisposition to blackwater fever.

(d) *Alterations in glucose*.—The importance of glucose for the growth and development of hæmo-protozoa, both *in vivo* and *in vitro*, has been demonstrated by several workers. So far as the malarial parasite is concerned the work of Hegner and MacDougall (1926) and of Bass and Johns (1913) fully justifies this view. The observation made by some other workers that glucose changes in the blood of malarial subjects have not indicated any distinct or significant alteration in every case studied (Rudolf and Marsh, 1927) cannot be interpreted as lessening in any way the importance of glucose as an essential factor in the growth of the malarial parasite. For we believe that the concentration of glucose in the blood will vary not only according to the intensity of the malarial infection but also according to the ability of the host to mobilize glucose in the blood.

This view is partly corroborated by the results of Otero (1932), and Tschilow and Mladenow (1934). The fact that in all intense infections in monkeys (Krishnan and Pai, 1936) a marked lowering of glucose invariably occurred suggests that under suitable experimental conditions it can be shown that a stage will be reached when the animal will be unable to mobilize the necessary glucose in the blood. This inability to mobilize glucose may be followed by, or be the result of, an upset in the carbohydrate metabolism. That such an upset does occur is indicated by the observation that an increase in the inorganic phosphorus of the blood is associated with the depletion in glucose, and the injection of glucose and insulin decreases the inorganic phosphorus. This altered metabolism of carbohydrates probably leads to the development of the hæmolytic agent and to a predisposition to hæmolysis and hæmoglobinuria. If this is so in monkeys, then it is conceivable how in some men, as a result of repeated attacks of malaria, the capacity of the body to utilize glucose in the normal way may be seriously altered, temporarily or permanently, and thus lead to a predisposition to blackwater fever.

The mere study of the glucose changes in the blood of blackwater fever cases may not indicate the extent of damage to carbohydrate metabolism and this may be the reason why such studies so far have not given any clue regarding any upset of the carbohydrate metabolism in man. That an upset of this metabolism does occur in man, as in the monkey, in the pre-hæmoglobinuric state is highly probable from other evidence as well. We believe that it is essential to consider this factor as being of far-reaching importance both in the ætiology and in the treatment of blackwater fever.

(e) *Alteration in inorganic phosphorus*.—The variations in inorganic phosphorus occurring in blackwater fever in man have been studied by a few investigators (Matko, 1918; Whitmore, 1928; Ross, 1932). Whitmore noticed an increase in this constituent but Ross obtained variable results. Matko advanced the view that alterations in phosphorus metabolism were responsible for hæmolysis, while Ross came to the conclusion that upsetting of the phosphorus metabolism was 'neither a preliminary to nor responsible for the intravascular hæmolysis'. The study of the alteration in this constituent in malarial hæmoglobinuria of monkeys (Krishnan and Pai, 1936) showed that there was a distinct tendency for the inorganic phosphorus to rise in the pre-hæmoglobinuric state in both splenectomized and non-splenectomized animals. In non-splenectomized monkeys not developing hæmoglobinuria, no such rise was noticed. This rise has been partly accounted for by these workers as being due to the rapid utilization of sugar through the hexose-phosphates of the corpuscles, and to the derangement of the carbohydrate metabolism. Their view appears to be

substantiated by the fact that diminution in inorganic phosphorus occurs in these cases as a result of the injection of glucose and insulin. From this it seems that the rise in inorganic phosphorus, if it occurs in blackwater fever, can not only be interpreted as being due to nitrogenous retention as shown by Ross (1932) but also as indicating a derangement in carbohydrate metabolism which appears to be an essential condition for the production of the hæmolytic agent. An absence of a rise in inorganic phosphorus does not necessarily indicate the contrary. Inorganic phosphorus may or may not be concerned directly with hæmolysis, but it does indicate the nature of the processes at work and the possible source and nature of the hæmolytic agent.

(f) *Alterations in organic phosphorus as lecithin.*—We are not aware of any work on the variations in organic phosphorus as lecithin in malaria or blackwater fever. The work of Krishnan and Pai (1936) in malarial hæmoglobinuria of monkeys shows that there is a marked increase in organic phosphorus in the pre-hæmoglobinuric state, that the increase is less pronounced in those not developing hæmoglobinuria, and least in those recovering from intense infection. This finding taken in conjunction with the rise in ester cholesterol observed (*vide supra*) suggests that as a result of intense malarial infection fatty acids are being produced and are accumulating and that one method of their disposal is by the formation of lecithin. It is difficult to say what part this rise in lecithin plays in hæmolysis. It seems that the alteration in the ratio between lecithin and free cholesterol is of some importance. When the ratio is high, conditions seem to favour the onset of hæmolysis and when it is normal or low hæmolysis is inhibited. It is also possible that the presence of lecithin in high concentration may lead directly or indirectly to the formation of hæmolysin. It would be interesting to study the variations in organic phosphorus as lecithin in human cases of blackwater fever, and until it is done it will not be possible to state whether in man there is a similar increase or not, whether it is brought about in a similar manner and whether it has a similar rôle to play. We believe that alterations in lecithin do play a part, directly or indirectly, in the hæmolytic process.

Is there a hæmolytic agent involved and if so what is its nature?

Hæmolysis of red cells may be due to a simple physical phenomenon like osmosis or to more complicated processes due to chemical agents. It is almost impossible to associate the hæmolysis leading to hæmoglobinuria in blackwater fever in man to merely physical phenomena. Although no one has been able to demonstrate the presence of a hæmolysin the assumption

that a hæmolysin is involved seems to be indispensable. If so, the three types of hæmolysins that have been suggested by different workers from time to time may be considered here:—(i) a auto-hæmolysin; (ii) a toxin of the malarial parasite; (iii) hæmolysins such as fatty acids arising out of an alteration in metabolism.

(a) *Auto-hæmolysin.*—Thompson (1924) observed some peculiar forms of red cells in malignant tertian malaria, and suggested that these may be antigenically different from normal cells and may give rise to hæmolytic antibodies. He believed that in blackwater fever cases these altered red cells were present in large numbers and that when the specific antibody was formed hæmolysis occurred. Normally, the body does not produce antibodies to its own red cells; it does so only if foreign red cells are introduced. Therefore, unless it can be shown that the abnormal red cells seen in blackwater fever cases are antigenically different from normal red cells, that they can induce the formation of antibodies, and that these antibodies are hæmolytic, this hypothesis cannot be accepted. Furthermore, the hæmolysin detected by a few workers in the sera obtained from some of the blackwater fever cases has not been shown to be of the nature of an auto-hæmolysin.

(b) *Toxin of malarial parasite.*—This hypothesis has already been discussed to some extent in the section on the 'biological strain' of the malarial parasite. Here it needs only to be emphasized that a 'biological strain' meaning a strain which is particularly capable of inducing pronounced metabolic changes and leading to the formation of hæmolytic substances in the body of the host is probably concerned. Such an assumption seems to be justified because that alone helps to explain the total absence of blackwater fever in certain hyperendemic malarial areas and the reputed house and familial distribution of cases in some localities. In view of the evidence presented in the other sections in this paper suggesting that profound alterations in the glucose and fat metabolisms in conjunction with a damaged state of the liver are the predisposing factors to hæmolysis the assumption of an exotoxin of the parasite seems to be unnecessary. Furthermore, no one has isolated it or described its qualities, and the onus of proof of this rests with those who make the assumption.

(c) *Hæmolysins such as fatty acids arising out of an alteration in metabolism.*—Several observers have found in chronic malaria evidence of an upset of the acid base equilibrium and a lowering of the bicarbonate reserve. This suggests that in the course of malaria there is overproduction of acid and that possibly this reaches a stage in some persons when hæmolysis can be readily caused. Blacklock and Macdonald (1928) have strongly supported this view and have incriminated lactic acid as a possible agent. The work of Ross (1932), however, shows that

although a condition of lowered bicarbonate reserve may be present in a certain percentage of blackwater cases, the change in the hydrogen-ion concentration is not enough to account for the hæmolysis. Recently, Ott (1932) has attempted to revive this fatty-acid theory on more or less hypothetical grounds.

In the case of monkey hæmoglobinuria Krishnan and Pai (1936) have obtained definite evidence of increased fatty-acid production (*vide supra*—rise in ester cholesterol and lecithin). Their work shows that in splenectomized monkeys, in which also the highest incidence of hæmoglobinuria occurs, the highest figures for cholesterol esters and lecithin were obtained. It is not known what the necessity for this abnormal and excessive production of fatty acid is; whether it is required for the parasite's growth and multiplication or for repair of damaged tissues or whether it is merely a by-product of altered metabolism, we cannot say. All the same it has been shown by these workers that associated with it the liver is damaged and the carbohydrate and fat metabolisms are upset. It can therefore be stated that so far as the monkeys are concerned hæmolytic unsaturated fatty acids are being produced in excess.

Some workers have opined that in monkeys the hæmoglobinuria being associated with an intense parasitization the hæmolysis can be explained on the basis of mere sporulation of the parasites. A closer study of the condition in these animals however has indicated that it would be necessary to assume here, as in man, that a hæmolytic agent is involved. The unsaturated fatty acids produced are more probably the agents of hæmolysis. In view of the high concentration of lecithin in the pre-hæmoglobinuric stage, it is even conceivable how hæmolytic substances like lyso-lecithin may be elaborated. The fact that the hæmolytic agent does not act when there is a sufficient amount of free cholesterol supports the view that unsaturated fatty acids or lyso-lecithin are probably the agents of hæmolysis. These acids we presume act not by virtue of their acid character but rather on account of their inherent hæmolytic properties. How far this fatty acid theory is applicable to blackwater fever cases in man it is too early to say. But we believe that it is the hæmolytic agent concerned in it as well. The beneficial results of alkaline therapy, glucose, choline hydrochloride, and cholesterol all lend support to this view.

Quinine hæmoglobinuria

Before concluding this article it seems essential to make a few remarks about the peculiar condition that is met with in certain cases of malaria and commonly classified under the term 'quinine hæmoglobinuria'. The existence of a number of such cases has given rise to the theory that improper drugging with quinine is responsible for the production of this condition.

The known facts relating to the condition are as follows:—The persons who generally develop it give a history of irregular and inefficient treatment with quinine. The condition is rare in those who have never taken quinine and also in those who have been properly treated with the drug. Administration of quinine even in minute doses precipitates an attack in these cases. It is however not known how the drug induces an attack of hæmoglobinuria or how it predisposes to it. That the drug does act as an excitant to hæmolysis and hæmoglobinuria in these cases, there is no doubt. The recent work of Nocht and Kikuth (1929) has shown that quinine *in vivo* favours hæmolysis and hæmoglobinuria when given with small doses of hæmolytic substances which in themselves are insufficient to produce either. This suggests probably that the agent responsible for the hæmolysis is not quinine itself but that the drug merely enhances the conditions favourable to hæmolysis already present. The processes of hæmolysis and hæmoglobinuria therefore do not seem to be different from those in the ordinary blackwater fever cases. If this view is correct then improper drugging with quinine merely acts as an adjunct to malaria in causing the damage which is an essential condition precedent to the onset of blackwater fever, and when the drug is administered later it elicits an abnormal response from the host and increases the chances of occurrence of hæmolysis and hæmoglobinuria. The work of Krishnan (1933) on the mode of action of quinine in malaria fully justifies such a hypothesis.

Conclusion

Taking all the evidence presented in the foregoing pages into consideration the following conclusion seems justifiable:—

Blackwater fever is not an independent disease but a manifestation of malaria. In its causation probably a special 'biological strain' of the malarial parasite is concerned. This strain is important not by virtue of its toxinogenic property but rather on account of its distinct biochemical activity. The peculiar mode of attack of the parasite on the host, for purposes of obtaining its food requirements, probably leads indirectly to the production of hæmolysis and hæmoglobinuria. This assumption recognizes the prime importance of the host factor not only in inducing this 'biological' variation in the parasite but also in producing the predisposition to hæmolysis and hæmoglobinuria. The two most important predisposing factors are a damaged reticulo-endothelial system and a diminution in free cholesterol involving both the red cells and the plasma, the latter determining the extent of hæmolysis and the former the degree of hæmoglobinuria. The sudden severe intravascular hæmolysis is explained not merely on the basis of physical alterations but rather by the presence of a hæmolysin. It is

suggested that this hæmolysin is the end result of a damaged liver and alterations in metabolism of both carbohydrates and fats, and that possibly it is of the nature of an unsaturated fatty acid or a lyso-lecithin.

ATEBRIN-PLASMOCHIN IN THE TREATMENT OF MALARIA

By D. MANSON, M.B., Ch.B. (Glas.), F.R.E.S.
Chief Medical Officer, Jorehaut Tea Co., Ltd.,
Cinnamara, Assam

Introduction

THE advent of atebrian and plasmochin into the realm of the chemotherapeutics of malaria was hailed with acclaim on all sides and the pendulum of public opinion swung rapidly upwards in favour of these new rivals to quinine. The new drugs were seized on with avidity, both by the medical profession and by the general public who were only too eager to escape from the thralldom of quinine, till then the sovereign remedy, albeit a remedy which offered no royal road to the goal of the 'magna therapia sterilisans'.

Both drugs were exhibited, sometimes in wrong doses, and the inevitable result was the appearance of a crop of reports, some laudatory, some damnatory, and some with the doubtful Scotch verdict of 'not proven'. The pendulum had commenced its downward swing. Since that time much has been written on the therapeutic action of atebrian and plasmochin and the dosages, particularly of plasmochin, have been altered and readjusted as the result of trial and error. One fact has emerged from the mêlée, namely, that these drugs have real merit and have come to stay. The present article was written as the result of trials with atebrian and plasmochin in revised dosages with a view to obtaining the most satisfactory therapeutic action and the lowest relapse rates.

Types of treatment

By the courtesy of the manufacturers, Messrs. Bayer-Meister Lucius, the writer was furnished with a series of tablets, etc., for use in this investigation.

The following types of treatment were chosen for trial :

- (1) Combined tablet of atebrian 0.1 gramme with plasmochin 0.0033 gramme.

(Continued from previous column)

(2) Combined tablet of atebirin 0.1 gramme with plasmochin 0.005 gramme.

(3) Atebrin tablet 0.1 gramme only.

(4) Atebrin-plasmochin dragées in same dosage as no. 1 but in keratinized capsules.

(5) Atebrin-plasmochin dragées in same dosage as no. 2 but in keratinized capsules.

(6) Atebrin musonate for injection, either intramuscularly or intravenously.

The object of the dragées was to determine whether the action of atebirin-plasmochin was interfered with in the stomach and whether possibly signs of intolerance or toxicity might be avoided when the drugs were liberated not in the stomach but in the bowel.

It was also proposed to note the action of the gastric juice in relation to the production of adverse symptoms and particularly the rôle of the gastric hydrochloric acid as a possible factor in cases which showed signs of intolerance or distress. Unfortunately the number of cases of abnormality in the gastric secretion met with in this experiment was limited to 5 cases in all and the results cannot be taken as definitely conclusive. Nevertheless these cases present some points of considerable interest.

In assessing the results of the various treatments, no cases are reported which have not been under observation for a minimum period of 6 months, and, in many instances, the period of observation is considerably longer.

No note was taken in these cases of the parasite densities in the peripheral blood as, in the experience of the writer, the intensity of infection has no relation either to the severity of the symptoms or to the relapse rate. As a matter of fact the smaller infections are often the most liable to relapse, either from lack of sufficient treatment or from the smaller degree of immunity resulting from the attack. In other words, the defensive mechanism is not roused to activity. It has also been the experience of the writer that cases of malaria with very few parasites in the peripheral blood often present more urgent symptoms of gastric distress, cerebral complications, or the asthenic type of malaria with grave algid symptoms.

James classifies the return of malaria after a primary attack in three categories:—

(A) *Recrudescence*.—A return of fever and parasites within 8 weeks of recovery.

(B) *Relapse*.—A return of fever and parasites between 8 and 24 weeks after recovery.

(C) *Recurrence*.—A return of fever and parasites at some time later than 24 weeks.

For clinical purposes there is no advantage in separating up recrudescence and relapse as specified above, and, in the tables printed below, this distinction is not made and all cases which showed fever and parasites within six months are classified as relapses.

It should be noted here that the area from which these cases were taken has been under anti-larval control for three years and that the

small number recorded represents the bulk of the malaria cases admitted to hospital for a period of 9 months. Thus, whilst reinfection cannot be entirely eliminated in assessing the relapse rates, this factor is not likely to be potent enough to vitiate the results. The population of the area from which these patients were received is roughly 25,000 and the area about 50 square miles.

All cases were treated in hospital and were kept under observation for not less than 7 days, during which time the blood was examined daily. On leaving hospital, a record was kept of all these admissions for 6 months, and every case was seen at least once weekly.

The results of treatment and the relapse rates are shown in table I.

Blood films (thick and thin) were taken daily in each case and the types of infection noted. The times of disappearance of parasites from the peripheral blood are noted in table II. Slides in every case were taken on completion of the day's treatment, so that, on the first day for example, each patient had 3 tablets before his blood was examined, and so on for each day. The table therefore shows the results obtained after 24 hours, 48 hours, etc., of the particular treatment specified.

A comparison of combined treatment with atebirin-plasmochin and atebirin alone shows that the combined treatment seems definitely to shorten the period of pyrexia by roughly one day on the average.

From the table it will be seen that there is little to choose between the four methods of treatment with combined atebirin and plasmochin, but that when atebirin alone is administered there is a definite prolongation of the life of parasites in the peripheral blood; this is if anything more marked in the case of atebirin musonate. Atebrin musonate was given in two doses of 0.250 gramme each, injected intramuscularly on successive days. The addition of plasmochin appears to shorten the time of persistence of the parasite in the peripheral blood.

In administering atebirin musonate, care must be taken to prepare the solution in the dark and also to keep the patient away from light as far as possible, following the injections. Unless precautions are taken, the drug exhibits some undesirable effects due to photo-synthetic action. If proper precautions are taken, no untoward symptoms arise.

Toxicity

A considerable literature has accrued on the subject of toxic symptoms following the administration of atebirin-plasmochin. A careful analysis of cases reported will show that these effects have often followed treatment carried out without proper control and often in patients not under hospital supervision.

There has also been a tendency to attribute symptoms which are due to malaria itself to

* Including one quartan case in which there was no relapse.

† Including one mixed infection case in which there was no relapse.

‡ Including one quartan case in which a relapse occurred.

the drugs administered. Symptoms arising from intercurrent disease have also to be excluded in estimating the effects of atebriin-plasmochin treatment. Green (1934) reports a case which developed epileptiform fits twenty days after treatment with atebriin. The patient, on questioning, admitted that he had had similar fits since childhood.

Again, abdominal pain and gastric tenderness are both common concomitants of a malaria attack and are independent of the drugs exhibited. Headache also is common in malaria and degrees of cerebral disturbance are met with in every severe attack.

In the present series of cases, adverse symptoms were surprisingly few. Three cases showed transient yellowish discoloration of the skin, associated with constipation.

Tropp and Weise (1933) have shown by colorimetric observations that atebriin is excreted in equal quantities in the stools and urine, and that the excreted pigment physically and biologically is identical with atebriin. If care is taken to prevent constipation and to promote diuresis by the plentiful use of fluids during the febrile period, yellow discoloration of the skin seldom occurs.

Hecht (1933) has shown that atebriin does not bring about the formation of methæmoglobin either *in vitro* or *in vivo*, and that the drug does not cause hæmolysis.

In the 106 cases reported in this paper, five only exhibited signs of intolerance. In these

five cases, gastric analysis showed abnormality in the secretion of HCl. Two cases showed hyperchlorhydria and three showed complete achlorhydria.

Case I.—Persistent hyperchlorhydria with subsequent development of gastric ulcer. This case developed benign tertian malaria and on completion of a five days' course of atebriin 0.1 gramme and plasmochin 0.005 gramme developed tachycardia, substernal tenderness and transient blueness of the lips and finger nails. The symptoms subsided quickly after cessation of treatment and the use of glucose by mouth.

Case II.—Benign tertian malaria and hyperchlorhydria. Completed the course of atebriin 0.1 gramme + plasmochin 0.005 g., t.d.s., but developed marked yellowness of the skin, tachycardia and slight abdominal pain. The symptoms, excepting the yellowness of the skin, subsided rapidly.

The subsequent history of this case is interesting. She relapsed and developed benign tertian malaria five months later. On my advice, she took atebriin 0.1 gramme with plasmochin 0.005 gramme in dragées. There were no symptoms of intolerance and there has been no further relapse within one year of treatment.

These two cases would seem to indicate that the presence of excessive hydrochloric acid was a possible factor in determining the symptomatology.

The experiments of N. D. Kehar (1935) seem to indicate that atebriin excretion, when the drug is administered on an empty stomach or 2½ hours after a meal, is greater than at, or within 2 hours of, a meal. This might also indicate a possible connection between the pH of the gastric juice and the absorption or retention of atebriin in the system.

Case III.—Achlorhydria. No free hydrochloric acid in gastric juice. Developed malignant tertian malaria. Treatment—atebriin 0.1 gramme + plasmochin 0.0033 gramme, t.d.s., in combined tablet. Blood negative on second day. On third day of treatment, patient complained of dyspnœa, pain in precordial region and

epigastric tenderness. Epigastric pain and tenderness persisted for days. The course of treatment was omitted on the fourth day and resumed on the fifth day with two tablets only daily.

Case IV.—Malignant tertian malaria—hæmoglobin 35 per cent (Hellige). Gastric juice showed no free hydrochloric acid. Treatment—atebrin 0.1 g. + plasmochin 0.0033 gramme, t.d.s. The patient complained of severe epigastric pain, nausea and vertigo on first day which persisted on second day. Treatment was stopped on second day but resumed on third day with atebrin 0.1 gramme + plasmochin 0.0033 g. in dragée, t.d.s. There was no further complaint of epigastric pain. Temperature was normal on fourth day. Blood positive until fourth day.

Case V.—Quartan malaria with nephritis, admitted on 23rd December, 1934. Gastric juice showed no free hydrochloric acid. The patient was pregnant. Treated with atebrin musonate 0.250 gramme intramuscularly on two successive days. Blood negative on second day. Patient complained of precordial distress and vertigo with epigastric tenderness. She aborted on the third day. Blood negative for next two weeks. Patient remained in hospital under treatment but relapsed on 14th February, 1935. Blood showed quartan malaria. She was treated with atebrin 0.1 g. + plasmochin 0.0033 gramme in dragée and had no complaint. Blood negative on seventh day.

In addition to these cases, two other cases, which are not included in this series, are of correlated interest :

Case A.—Female with complete achlorhydria and cholecystitis, treated for malignant tertian malaria, with atebrin 0.1 g. and plasmochin 1/6th grain daily. Developed signs of intolerance with gastric and abdominal pain and cardiac distress, and vomiting on second day. Subsequently given quinine.

Case B.—Female. Gastric secretion normal. X-rayed for bilious attacks. Well marked cholecystitis. She developed malignant tertian malaria and was treated with atebrin-plasmochin. The dose given was atebrin 0.1 gramme in tablet form. To this was added plasmochin 1/6th grain daily on the second day of treatment. She developed signs of intolerance after 24 hours with severe gastric pain, tenderness on the liver and headache. Blood negative on second day. This patient has since been operated on for cholecystitis.

These two latter cases are not included in the 106 cases recorded in the above series, but are noted as they seem to bear on the five cases reported above.

From the evidence of these cases, there seems to be a definite connection between achlorhydria, the biliary system, and the production of toxic symptoms after the exhibition of atebrin and plasmochin.

It seems logical to conclude that the symptoms of intolerance in these cases after the administration of these drugs were due to abnormality of the gastric juice alone or accompanied by pathological changes in the gall-bladder.

In none of the remaining 101 cases were any untoward symptoms evolved.

Hecht has shown by making use of the fluorescent effect of atebrin under the influence of ultra-violet rays, in experiments on mice, that atebrin is retained markedly in the gall-bladder and less markedly in the bowel and liver.

It seems reasonable to infer that such retention may cause the production of toxic symptoms when the gall-bladder is already the seat of pathological changes with deficiency or slow excretion of bile. It seems also a reasonable inference that, in normal individuals, the exhibition of atebrin and plasmochin in the doses devised for these experiments is perfectly safe and not likely to produce any toxic symptoms.

The scope of this paper does not permit any evaluation of the parts played by atebrin and by plasmochin or which of the two assumes the leading rôle. In the doses used, it is clear that plasmochin is well tolerated.

The effects of treatment

The results show a relapse rate of 11.32 per cent within 6 months. This rate compares very favourably with the relapse rate of quinine-treated cases. The relapse rate with quinine in a series of 200 cases treated on three gardens during 1930-31 was 40 per cent. Not only is the relapse rate reduced from 40 per cent with quinine to 11 per cent with atebrin-plasmochin, but the bulk of the patients infinitely prefer the atebrin-plasmochin treatment to quinine, in whatever form. The period of treatment is also much shorter and this is a factor of considerable commercial value.

A comparison of treatment in table II shows that the combined treatment is better than atebrin alone.

Regarding the combined treatment, the results obtained by atebrin-plasmochin in dragées are better than with the combined tablet, and toxic symptoms are avoided. There is nothing to

choose between the two doses of plasmochin so far as results go.

Duration of fever

The average duration of fever in these cases was closely correlated to the presence of malarial parasites in the peripheral blood, and fever usually abated when the blood was negative.

In a few cases fever persisted for about twelve hours after the peripheral blood was negative. The average duration of fever was therefore about 48 to 60 hours.

Treatment of relapses

Relapses were treated with atebirin 0.1 gramme + plasmochin 0.005 gramme, t.d.s., for

5 days. Treatment was omitted for the next 3 days, and a subsequent treatment of atebirin alone for 3 days given, the dose being 0.1 gramme, t.d.s. The blood is examined daily during this course. Blood is examined on completion of the second short treatment. The patient is then put on quinine gr. x daily at night for 10 days. At the end of the period, the blood is re-examined and, if negative, atebirin alone, 0.1 g., t.d.s., is given for 3 days. This completes the treatment. So far none of the cases so treated has relapsed. The treatment is designed to anticipate the possibility of relapse about the beginning of the third week after the initial attack.

Atebrin musonate

Only 5 cases were treated in this series with a relapse rate of 20 per cent. Two injections only were used on consecutive days. Some modification of this treatment would seem to be essential and more extensive trial is necessary before any conclusions can be drawn.

Summary

Atebrin-plasmochin in combined tablet and in dragées and atebirin musonate in the various doses were tried in a series of 106 cases. The relapse rate was 11.32 per cent. Excluding the atebirin musonate series in which one out of five cases relapsed and the atebirin only series in which the relapse rate was 15.38 per cent, the relapse rate with atebirin-plasmochin combinations was 9.33 per cent.

The small difference in the dose of plasmochin in the combined tablets or dragées had no appreciable influence on the results.

Toxic symptoms in this series were limited to cases which showed excess or deficiency of gastric hydrochloric acid or pathological changes in the gall-bladder. No toxic symptoms were noted in normally healthy patients. The percentage of cases showing toxic symptoms was 4.7. Atebrin-plasmochin in dragées form was successfully exhibited where the ordinary tablets caused epigastric distress. This bears out the relation of the gastric pH to the production of toxic symptoms.

A scheme for the treatment of relapse is outlined.

Conclusions

Atebrin 0.1 gramme with plasmochin 0.0033 or 0.005 gramme given in dragées is the best treatment for malaria at present available, with the lowest relapse rate.

Atebrin musonate requires further trial before a definite conclusion can be arrived at. The dosage is probably insufficient.

Atebrin-plasmochin dragées are least likely to cause symptoms of intolerance, even in the presence of gastric or biliary disease. No relapses occurred in the series, in which dragées were used.

MASS TREATMENT WITH INJECTABLE ATEBRIN

By A. T. W. SIMEONS, M.D. (Heidelberg)
Bombay

IN the course of experiments conducted at the Colombo General Hospital during the malaria epidemic in Ceylon with atebirin-dimethylsulphonate (musonate) a method was elaborated by which it became possible to effectively treat severe cases of malaria with two injections given at an interval of 24 hours without any other additional treatment (Blaze and Simeons, 1935).

The results obtained in these experiments showed that it is possible to exercise a very rapid and lasting effect on a malaria infection by this particularly simple method. Although it is usually possible to cure a case of malaria with oral atebirin only, it is obviously a great advantage to have a simple, effective and quick treatment in certain cases. Apart from those very severe cases where quick results are urgently required this method would seem to have particular and hitherto unrealized advantages for conducting a 'blanket treatment'. It was therefore desirable to continue my experiments on a larger scale under well-controlled conditions permitting exact observation.

'Blanket treatment' of hospital staff

For this purpose the staff of the Kurunegalle Hospital was selected. Kurunegalle is a provincial town in Ceylon situated in one of the worst epidemic centres. The hospital staff consists of 65 persons, practically all of whom had had malaria within the last two months. Thirty-eight were actually suffering from clinical symptoms at the time and on an average there was a daily absence of about 20 per cent, in spite of the fact that nearly all were taking quinine or quinoplasmochin in varying doses. Twenty-eight persons had enlarged spleens and 36 blood slides were found to contain parasites

(Continued from previous column)

Acknowledgments

The writer thanks Dr. A. Brocke, Ph.D., of Bayer-Meister Lucius for supplying the drugs for these experiments.

He also acknowledges the assistance of Dr. L. R. Dey and the staff of the Cinnamara Central Laboratory for their help in the compilation of the tables.

MALARIA & RAINFALL IN GOKAK MILL AREA 1929 ~ 1935.

(22 malignant tertian, 11 benign tertian and 3 malignant tertian *plus* benign tertian mixed infections). The staff was requested to take no medicine for 24 hours and every person was then given an intramuscular injection of 0.3 g. injectable atebirin (musonate) dissolved in 9 c.c. of sterile distilled water. The same injection was repeated on the following day and the staff was instructed to take no further medicine.

The blood of every person was re-examined three days after the last injection. In one case 2 degenerated benign tertian parasites were found in a thick film; not a single healthy parasite was seen in any of the slides. Every slide was independently studied by two observers.

After the first injection two sisters complained of a slight feeling of giddiness and one doctor vomited. No other unpleasant symptoms were observed. In fact nearly all the patients spontaneously expressed a distinct feeling of well-being after the second injection. In every case the injection itself proved absolutely painless, two or three persons however complained of a slight tenderness some time after the injection. Routine work was continued without any interruption before and after the injection. No case of fever attributable to malaria was observed during the following 5 weeks in spite of the fact that the possibility of reinfection could not be excluded. Six weeks later 6 cases of malaria were observed: (malignant tertian 2, benign tertian 4). During an epidemic it is of course impossible to say whether these were relapses or reinfections.

This experiment proved the suitability of parenteral treatment under working conditions in a well-controlled group of persons.

Mass treatment in an isolated village

The next step was to find out whether this method could be used under field conditions in an uncontrolled population. For this purpose a small isolated village with about 250 inhabitants in the Kurunegalle district was selected, the death rate in that village being the highest in the whole area (60 registered deaths in two months).

One hundred and forty-six blood slides were examined of which 58 (39.72 per cent) were found positive (benign tertian 17, malignant tertian 37, benign tertian *plus* malignant tertian 4). Every inhabitant received 2 injections, 24 hours apart, of injectable atebirin (0.3 g. in 9 c.c. water). Children were given 1 c.c. of the solution per year of age up to 8 years; children above 8 years receiving the full dose.

One week later 124 blood slides were taken from persons previously injected of which 6 were found to be positive (4.5 per cent) (benign tertian 4, malignant tertian 2). Not a single inhabitant complained of having had any fever at all during this week. The population was carefully controlled over a period of 6 weeks during which time 7.6 per cent of the treated

persons complained of having had fever. Here again it was obviously impossible to distinguish between relapses and reinfections.

The whole treatment was carried out in 3 days. The general condition of the inhabitants before treatment was extremely bad through continued fever and famine but improved remarkably immediately afterwards. Two small children, 2 and 4 years of age, were suffering from cerebral malaria, were unconscious and having convulsions. As their condition seemed hopeless, the risk of injecting was taken. One child died in a collapse about 20 minutes later, the other child vomited but made a complete recovery in 48 hours. In 3 other children vomiting and giddiness were observed; these symptoms, however, passed off in a few minutes leaving no undesirable after-effects. Those persons injected on the first day felt so much better that no difficulty was encountered in administering further injections.

The above-mentioned toxic effects in children induced the medical authorities of Ceylon to pronounce injectable atebirin unsuitable for mass treatment in an under-nourished population. Further experiments on this line were therefore broken off, the atebirin musonate treatment being reserved for special cases only.

Mass treatment in a mill area

An opportunity for further experiments in mass treatment was however offered by a Bombay firm who, having heard of the work in Ceylon, were prepared to carry all expenses for a 'blanket' treatment in one of their mills with a very heavy incidence of malaria.

A preliminary survey of the malaria at the Gokak mills in the Southern Mahratta country showed ideal conditions for conducting a carefully-controlled experiment. The mill is situated on the bank of a river and includes a village for mill-hands with a total population of about 5,600 souls. There are no other villages within a radius of about 3 miles of the mill area. All illness occurring in the village is treated in the mill hospital by a resident medical officer and careful records are kept. The carrier is *Anopheles culicifacies* which breeds in the river bed (no other breeding places were found in the vicinity). The chart shows the monthly incidence of malaria for the last 7 years in relation to the monthly rainfall. From the chart it can be seen that during the years 1926 to 1932 there is an increase in yearly rainfall and a decrease in malaria incidence. After 1932 the yearly rainfall drops or sets in late while the malaria incidence rises. Owing to a long drought from November 1934 to May 1935 there is an unusually high malaria peak, reaching 880 cases in the month of April.

After one week of careful oiling of all breeding places in the river bed, a blanket treatment of the whole population was started on the 27th of May 1935. Five thousand six hundred

and fifty people were treated (11,300 injections). This work was completed within 9 days with the help of two assistants. As it was intended to show that this method can be carried out in a minimum of time with negligible overhead expenses neither parasite rate nor spleen index were recorded. Every person in the mill area was treated including infants, pregnant women and persons suffering from other diseases.

The dosage of each injection (24 hours apart) was as follows:—

Strong and healthy adult males 9 c.c. (0.3 g. atebtrin).

Strong and healthy adult females 8 c.c.

Weak or unhealthy adult males 8 c.c.

" " " " females 7 c.c.

In the case of children dosage was not given according to stated age but rather according to general appearance approximately as follows—

Infants appearing to be below 6 months $\frac{1}{2}$ c.c.

Above 6 months and up to 2 years 1 c.c.

2 to 4 " 2 c.c.

4 " 6 " 3 c.c.

6 " 10 " 4 c.c.

10 " 12 " 5 c.c.

12 " 15 " 6 c.c.

15 " 18 " 7 c.c.

A small dose of magnesium sulphate was given to every person before the first injection.

After the second injection every patient was given 3 tablets of 0.02 g. plasmochin simplex (children correspondingly less) and instructed to take one tablet on three consecutive days beginning on the day after the second injection.

The only toxic symptoms observed after the injection of atebtrin were a slight giddiness in about 1 per cent of the cases and three cases of fainting, none of which were serious. No mental derangement of any kind was observed.

The percentage of persons complaining of giddiness after the injection was slightly higher in those injected in the afternoon than in those that received their injection early in the morning. This seemed to suggest that the injected solution which was prepared in large quantities in the morning gradually deteriorated during the day. In order to get some more definite information on this point 500 doses were prepared one evening, kept overnight and injected the following morning. Out of this batch about 50 to 60 persons complained of giddiness within the next 5 or 6 hours. It was therefore decided to prepare smaller quantities of solution at a time and to discard any solution that could not be used at once. From then on out of about 3,500 injections only one case of giddiness was observed.

Since these observations Hecht has informed me that he has carried out pharmacological experiments which definitely show that no toxic

substances are formed when atebtrin-dimethylsulphonate solution is submitted to severe stability tests; it deteriorates only very gradually under normal conditions. Whatever the explanation of my observation may be the fact that the manufacturers put up the preparation in dry ampoules seems to emphasize the importance of using only freshly prepared solutions.

During the first half of the treatment the refilling of the syringe was done by means of a rubber tube from a bottle containing the solution attached to an adaptor with a three-way cock fitted to the syringe. In this way it was possible to refill the syringe rapidly under perfectly aseptic conditions. About half-way through the work, however, these adaptors began to leak and it became necessary to immerse the syringe into the solution for refilling, not a strictly aseptic procedure. The result was that whereas among patients injected with the adaptor no abscesses occurred, 49 cases of abscesses, mostly in young children and old and feeble adults, were observed among those injected during the latter part of the treatment. As it is known (Hicks, 1935) that the injection does not give rise to necrosis, I am inclined to believe that these abscesses were due to an unsatisfactory asepsis rather than to the injection itself.

The only serious incident was hæmoglobinuria occurring on the day after the last tablet of plasmochin (4 days after the second injection). In all, 4 cases were observed, 2 severe cases ending fatally and 2 mild cases. All 4 patients were Mohammedans, 3 belonging to the same household and all four natives of the same village situated a few miles further up the river, but all at the time residing in the mill area. All were taking treatment from a local physician for syphilis.

The two fatal cases were known to have been suffering from syphilis. The two mild cases, young brothers, believed that they were suffering from 'venereal disease', but had no specific history. All had previously suffered from malaria but were quite free of clinical symptoms at the time of treatment. The cases resembled in every respect those observed and described by Amy (1934) in the North-West Frontier Province of India. It is most unfortunate that laboratory facilities were not available for a detailed study of my cases. Of the two fatal cases one, a young man, died in 48 hours, the other made an apparently complete recovery but left hospital against orders and died 2 days later in his house of heart failure, an occurrence not uncommon in true blackwater fever.

There is nothing to suggest that these cases had anything to do with the atebtrin (Chopra, Sen and Bhattacharya, 1935). They appear to be in some way connected with plasmochin. Perhaps the fact that all four were taking medicine (mercury?) may help to throw some light on this perplexing problem, although I

have received a private communication from Col. Amy that there was not even a suspicion of syphilis in any of his cases.

Except one not quite typical case described by Lindberg (1935) blackwater fever as such is unknown in the Gokak district.

Immediately after the mass treatment, not a single case of malaria was observed. Through the carefully conducted anti-larval campaign I tried to exclude as far as possible a reinfection after the mass treatment so that all cases of fever occurring after treatment could be registered as relapses.

In spite of the fact that an occasional reinfection may have been included among the registered relapses, the figures, as can be seen from the chart, are surprisingly low considering the fact that no quinine or other anti-malarial remedy has been dispensed during the 7 months of observation. The total numbers of malaria cases for each month after the blanket treatment are as follows:—

June	2
July	10
August	5
September	9
October	6
November	15
December	8

Every relapse has been immediately treated with 2 injections and the villagers (after extensive propaganda) seem to have realized the importance of bringing every fever case for treatment so as to prevent a further spread.

Discussion

The first experiment (Kurunegalle Hospital) shows that my method, *i.e.*, the treatment of a case of malaria with two injections of atebtrin-dimethylsulphonate at an interval of 24 hours, is practicable without interference with the routine work of the treated person. The two field experiments, one in the Ceylon village and the other at Gokak, show that my method is particularly suitable for blanket treatment and it therefore appears to be a useful addition to our therapeutic armament.

The method was originally devised for the treatment of the actual acute malaria attack. In this respect I am inclined to consider the results satisfactory.

It is only from the Gokak experiment that we can gather some information regarding the relapse rate after this abbreviated treatment. Here too I am inclined to consider the results better than were to be expected considering the very small quantity of atebtrin given. I am, however, not surprised by the fact that other authors have found a higher relapse rate after two injections of atebtrin musonate, as it must be borne in mind that my experiments were all conducted in highly endemic areas during a particularly high incidence. We must presume

that the population in these areas had already acquired a considerable degree of immunity and that therefore very small doses of atebtrin were sufficient to produce good and lasting results. On the other hand when dealing with first infections it will probably be necessary to give a longer treatment in order to prevent relapses and achieve a permanent cure, be it by an oral after-treatment or further injections at longer intervals.

Summary

(1) A hospital staff of 65 persons received two injections of atebtrin-dimethylsulphonate at an interval of 24 hours. Parasites and fever were completely controlled in 3 days. No further malaria fever was observed during the following 5 weeks. No serious toxic symptoms were observed.

(2) During a malaria epidemic in a village in Ceylon, all inhabitants including children (240 persons) were treated with two injections. Every person so treated was free from clinical symptoms of malaria during the following week. Before injection the parasite rate was 39.72 per cent; one week after injection the parasite rate was 4.5 per cent. During the next 6 weeks 7.6 per cent of the population complained of having had fever. The general condition of patients very considerably improved immediately after treatment.

(3) In a mill area blanket treatment of 5,650 persons with two injections was completed in 9 days. Solution more than a few hours old produced giddiness in a small percentage of persons and very occasionally fainting. The former symptom was only observed in one case with fresh solution. Forty-nine abscesses in small children and weak adults are ascribed to unsatisfactory asepsis and not to the injection as such. Four cases of hæmoglobinuria after plasmochin are observed in patients who are receiving anti-syphilitic treatment from a hakim. A possible connection between syphilis, mercury, plasmochin and hæmoglobinuria is suggested. During the 7 months a total of 55 relapses was observed, and treated with two injections as before.

Acknowledgments

My thanks are due to the medical authorities in Ceylon for permitting preliminary experiments and to Messrs. Forbes, Forbes, Campbell and Company, Bombay, for their support and help in carrying out the mass treatment at Gokak.

To Dr. Malshett, the resident medical officer at Gokak, and to my assistants Doctors Devasahayan and Swamidass for their enthusiastic co-operation.

RHEUMATIC HEART DISEASE IN THE BOMBAY DECCAN

By L. B. CARRUTHERS, B.A., M.D., C.M.
American Presbyterian Hospital, Miraj, S. M. C.

THE conception that rheumatic fever and its concomitants are rare or entirely unknown within the true tropics has long been in favour. Seemingly it received strong confirmation when Clarke (1930) published his notable paper on the geographical distribution of rheumatic fever. Rogers and Megaw (1930) in India and Swift (1931) and Longcope (1931) in America have supported this view. However, in the same year that Clarke published his paper, Hughes and Yusuf (1930) reported 25 cases of heart disease of rheumatic origin from Lahore, while Stott (1930) at Lucknow reported 20 cases of mitral stenosis. Two years later, Hodge (1932) reported six cases of rheumatic disease from Jalpaiguri, Bengal. Nevertheless, in each of these cases the objection can be made that they were not from within the true tropics. More recently, Kutumbiah (1935) from Vizagapatam and Banerjee (1935) from Calcutta have published series of cases of rheumatic heart disease to which this objection cannot be taken. It is our purpose to help further to clarify this subject by reporting our experience at Miraj.

Miraj is situated in the Bombay Deccan, 160 miles south of Poona at an elevation of about 1,800 feet and well within the true tropics. The Presbyterian Mission Hospital is an institution of 270 beds caring for about 5,500 outpatients and approximately 3,200 inpatients yearly, the majority of the latter, namely 70 per cent, being surgical. In the period under discussion, from 1st November, 1933, until 1st November, 1935, there were 6,248 admissions to the hospital, 4,281 (68.52 per cent) being surgical and 1,967 (31.48 per cent) being medical. During this period of time there were 100 cases of cardiac disease admitted, distributed according to diagnosis as shown in table I. These formed 1.60 per cent of the total admissions and 5.08 per cent of the medical admissions. In this group there were 47 cases of rheumatic origin, forming 0.75 per cent of the total admissions and 2.44 per cent of the medical admissions. In reference to the temperate climates, Tice (1920) states that about 5 per cent of all patients met

with in general practice have chronic valvular disease of the heart and Davis and Weiss (1931) have found that rheumatic heart disease made up 9.1 per cent of 5,215 autopsies performed in Boston. Although there seem to be no statistics for the incidence of rheumatic heart disease in hospital practice in the temperate zones that

Note.—Among the rheumatic hearts, paroxysmal auricular fibrillation and chronic auricular fibrillation were each seen twice.

are strictly comparable with those herewith presented, nevertheless there seems to be little doubt, in the present state of our knowledge, that the condition is much less prevalent in the Bombay Deccan.

Discussion

The greatest difficulty in classification was experienced in the arteriosclerotic-hypertensive group of cases. In general, it may be said that we have put all cases showing a marked degree of peripheral arteriosclerosis, a well-marked aortic sclerosis or cardiac pain in the arteriosclerotic group. Those cases that showed a persistent hypertension without marked vessel sclerosis were considered as purely hypertensive while those cases that showed neither hypertension nor arteriosclerosis but were associated with pulmonary emphysema were classified as such. In this way, we were able to classify 11 per cent of our cases as hypertensive and 28 per cent as arteriosclerotic. As Fahr (1935) remarks, 'there is often considerable doubt as to whether a case should be filed as a hypertension heart or as coronary disease and the final decision is somewhat arbitrary'. Further the part played by the pulmonary factor is often difficult to assess in many cases. Maher *et al.* (1935) found 26.2 per cent of their cases in the Chicago area to be hypertensive and 24.1 per cent to be arteriosclerotic. These figures do not include their pulmonary cases which formed an additional 5.8 per cent. These three formed 56.1 per cent of their total cases as compared with our 39 per cent. Comparison of our percentages with these and other figures is shown in table II. It will be noted that we report having seen no case of congenital heart disease nor of thyroid heart disease in this present series. Maher *et al.*, on the other hand, reported 0.6 per cent and 10 per cent respectively for these types.

In considering our cases of rheumatic heart disease with which we are primarily concerned in this paper, we note that they made up 47 per cent of our 100 cases as compared with 43.2 per cent of the series reported by Kutumbiah from

TABLE II

	Miraj	Cabot (Boston)	White and Jones (Boston)	Maher <i>et al.</i> (Chicago).	Perry (England)
Rheumatic	47.0	32.0	30.0	29.2	38.4
Senescent	39.0	60.0	57.3	56.1	31.8
Syphilitic	10.0	7.0	2.9	0.97	6.5

Vizagapatam and 33.2 per cent of that reported by Banerjea from Calcutta. Of these 47 cases of rheumatic heart disease, eleven were females

and 36 were males. Torrey (Tice, 1920) states that the total incidence of rheumatic fever in males and females probably does not present any great differences, records from private sources being much more trustworthy on this point than are the history records from hospitals. Females are more apt to be treated at home in all parts of the world and this is especially true in India.

Cabot (1926) in a series of 239 cases reports the onset below the age of ten in 45 or 18.8 per cent, below the age of twenty in 125 or 52.3 per cent and below the age of thirty in 172 or 72.1 per cent. The figures in our much smaller series are as follows: below the age of ten 17 per cent, below the age of twenty 44.68 per cent and below the age of thirty 64.68 per cent. This would indicate a slight but definite tendency to a later age of onset in India. The age of onset in our series is shown in table III.

TABLE III

50 and over	1	..
TOTAL ..	36	11

Of our 47 cases of rheumatic heart disease, 35 or 74.4 per cent gave a definite history of joint pains and of these, twelve showed these symptoms during their stay in the hospital. Cabot reported that of 92 cases, 78 per cent had rheumatic arthritis as a factor, while tonsillitis seemed important in only 7 per cent. In these cases, 6 per cent had had chorea whereas none of our cases gave such a history. Our figures are compared with Cabot's in table IV. Twenty-five of our 35 cases with definite rheumatic history also showed infected tonsils. Making up the 12.7 per cent of cases showing

TABLE IV

Type of infection	Miraj, per cent	Cabot, per cent
Rheumatism ..	74.4	78.0
Tonsillar infection	12.7	7.0
Chorea ..	0.0	6.0
Other infections	12.7	7.6

'other infections' which may or may not have been of aetiological importance was one case with chronic otitis media, three cases with severe pyorrhoea alveolaris and two cases of intestinal parasites. The fact that our incidence of

rheumatic history approximates that obtained by Cabot in Boston does not run parallel to McLean's (1932) observation that the incidence of rheumatic carditis without a history or other clinical evidences of rheumatic fever is 50 per cent greater in Alabama than in New York.

An attempt has been made to judge and compare the severity of the cardiac damage done by the rheumatic infection. This is done in table V by a comparison of the number of valves involved. Both Cabot in his book on physical diagnosis and Lewis (1933) are agreed that mitral regurgitation of rheumatic origin is but the first step in a pathological entity that later will cause stenosis also. Lewis further maintains that many cases of regurgitation will reveal the stenotic murmur on more careful examination. The procedures he recommends have not always been employed in our cases and, as a result, we make no attempt to separate our early cases of mitral disease from our late ones. Since a number of our cases that are classified as combined mitral and tricuspid lesions are undoubtedly pure mitral cases with functional tricuspid regurgitation, this being a strong possibility in at least four of our five cases, the conclusion seems justifiable that multiple rheumatic valvular involvement is distinctly less common among the cases that we see.

Paroxysmal auricular fibrillation and chronic auricular fibrillation were each diagnosed twice in our series of rheumatic cases. These were not checked by electrocardiography. Subcutaneous nodules were not seen. Of our 47 cases, 27 were discharged as improved, seven were sent home as unimproved or distinctly worse and 13 died in hospital. Of these 13 deaths, seven cases came to autopsy. The results of these autopsies are summarized below. In two cases the mitral deformity was typically funnel-shaped.

THE PROGNOSTIC VALUE OF THE VARIATION IN THE ARNETH COUNT IN CASES OF ASTHMA TREATED WITH AUTO-VACCINE

By L. EVERARD NAPIER, M.R.C.P. (Lond.)
and

DHARMENDRA, M.B., B.S.
The School of Tropical Medicine, Calcutta

ACTON and Dharmendra (1933) noted that in the allergic cases of asthma the Arneth count

(Continued from previous column)

As a result of the study of this series of cases we feel ourselves justified in drawing the following conclusions:

(1) Rheumatic fever, as shown by the presence of rheumatic heart disease, although not as prevalent as in other parts of the world, nevertheless is a common condition in the Bombay Deccan.

(2) The percentage of heart disease that is rheumatic in origin is greater than in other parts of the world.

(3) There would seem to be a slight but definite tendency to a later age of onset in rheumatic heart disease in the Deccan.

(4) The percentage of rheumatic heart disease without clinical evidence of rheumatic fever is no greater in the Deccan than elsewhere.

(5) The cardiac involvement in rheumatic fever in the Deccan does not seem to be so severe as in the north-western United States.

was usually normal, while there was a marked shift to the left in the count in the bronchial cases which are dependent on some infection. By a 'shift to the left' is meant an increase in the single-lobed and two-lobed cells—the less mature forms—and a decrease in the multi-lobed, the more mature granulocytes. They observed that the Arneth index (sum of the number of cells with one and two-lobed nuclei and half the number with three-lobed nuclei) was generally below 70 in the allergic cases and above 70 in the bronchial cases.

In the present paper we have reported the changes in the Arneth counts produced by means of treatment with auto-vaccine in cases of asthma. Observations on 25 such cases have been recorded. In all the cases a vaccine

but in whom the symptoms returned after varying intervals of time. The third group of 11 patients who were definitely relieved of the symptoms and who have remained free so far (the second count in all the cases except one were done between December 1934 and July 1935).

When the variations in the Arneth count on the two occasions are correlated with these three clinical groups the relation between the improvement in the condition of the patient and the improvement in the shift to the left in the Arneth count becomes apparent.

The table shows that in group I in three cases there was an actual rise in the index, in one case there was no change, and in three cases a small fall after the treatment. In group II, in

TABLE

	Total number of cases	Number of cases in which the Arneth index increased	Number of cases in which there was no change in the Arneth index	NUMBER OF CASES SHOWING DECREASE IN THE ARNETH INDEX			
				Decrease of			
				5 or less	6 to 10	11 to 15	16 to 20
Group I Cases in which there was no appreciable improvement after the vaccine treatment.	7	3	1	3
Group II Patients who were relieved of their attacks but in whom the symptoms relapsed at varying intervals after the treatment.	7	..	1	2	4
Group III Patients who were relieved by the treatment and have so far remained free from attacks.	11	3	5	3

made from the organisms isolated from the sputum was used and a course of six injections was given. The first count was done on admission of the patient to the hospital and the second about two days after the last dose of the vaccine. In all the cases the Arneth count on the first occasion showed a marked shift to the left. At the second examination the count showed an even more marked shift to the left in three cases, no change in two cases, and a decrease in the shift, either slight or marked, in 20 cases.

From the point of view of the result of the treatment these 25 cases can be divided into three groups. The first group consisting of seven patients who showed no appreciable improvement in their symptoms after the course of the treatment. The second group consisting of seven patients who were definitely relieved

one case there was no change while in the other six cases there was a varying amount of fall in the index. In group III in all the eleven cases there was a fall, and in most cases a marked fall, in the index, i.e., a decrease in the shift to the left.

Figure 1 shows in graphic form the level of the Arneth index before and after treatment and the extent of the increase in the stippled areas—and of the decrease—the shaded areas—during treatment, that is, the increase or decrease, respectively, in the shift to the left of the Arneth count.

Figure 2 shows only the extent of change in the shift in the Arneth count after treatment with auto-vaccine. The shaded areas above the base line indicate the extent of decrease in the Arneth index, i.e., of the improvement in the shift to the left in the Arneth

count. The stippled areas below the base line show the extent of the change in the opposite direction. it fall by more than four; in group II the index fell by 3 to 10; in group III it fell by 10 or less in three cases and in the other eight cases

Figure 1 showing the Arneth indices in the 25 cases before and after treatment with auto-vaccine. The stippled areas indicate the extent of the increase and the shaded areas the extent of the decrease in the Arneth index during treatment.

Group I. Patients not much improved by the treatment. Group II. Patients definitely relieved but relapsed. Group III. Patients definitely relieved and remaining free from attacks so far.

It will be noted that in group I in three cases the index actually rose and in no case did the fall was more than ten. The same results are shown in the table.

From the above observations the following conclusions become evident:—

(1) The initial Arneth count gives little information about the results to be expected from vaccine treatment. The initial indices in all the three groups ranged (*vide* figure 1) between 80 and 95 in most of the cases; only in two cases in group III was the index below 80.

(2) The Arneth count after the treatment gives some information on this point. In all

favourably to the treatment the index sometimes rises and in no case shows a marked fall. In the cases showing temporary improvement the fall in the index never exceeded 10 points. While in the third group of cases the fall was less than 10 in only three, and the remaining eight showed a fall of between 11 and 20 points. It can thus be said that a fall of 10 or more in the Arneth index after the treatment with auto-vaccine is a good prognostic sign.

Figure 2 showing the extent of change in the shift to the left in the Arneth count after treatment with auto-vaccine. Figures above the base line indicate the extent of decrease in the Arneth index; figures below the base line show a change in the opposite direction.

the cases in group I the Arneth indices after the treatment were above 80, in group II only in two cases were they below 80, but in group III in every case except one the indices were below 80. The fall of the Arneth index below 80 seems to be a favourable prognostic sign.

(3) The extent of fall in the index after the treatment gives the most information regarding the prognosis (figure 2 and table). It will be seen that amongst the cases not responding

A similar correlation between the improvement in the condition of the patient and in the Arneth count has been reported in cases of tuberculosis. Hamilton-Black (1913) observed that in certain cases of tuberculous disease tuberculin treatment improved the Arneth count, making the shift to the left less marked. Holroyd (1913) noted that in cases of tuberculosis the improvement in general condition was

(Continued at foot of opposite page)

A CASE OF IRON ENCEPHALOPATHY

By L. EVERARD NAPIER, M.R.C.P. (Lond.)
School of Tropical Medicine, Calcutta

AN Indian male, aged 30 years, a casual labourer, was admitted to the Carmichael Hospital for Tropical Diseases on 28th October,

(Continued from previous page)

accompanied by an improvement in the shift to the left in the Arneth count. Kennedy and Flint (1930) found that the Arneth count in cases of surgical tuberculosis treated by natural heliotherapy in the Alps showed a much less degree of shift than in the cases treated in Britain.

Clinical analysis of those in which there was no or only temporary improvement

(1) Amongst the seven cases not responding to vaccine treatment two had definite tuberculous lesions in the lungs, shown by a skiagram of the chest. In one the asthma was not of a bronchial type but of the allergic type (due to dust sensitiveness) and later this patient was relieved by means of hypo-sensitization with the dust extract.

(2) Amongst the seven cases showing temporary relief the skiagram of the lungs showed early tuberculous lesions in the two cases and healed tuberculosis in one case. In one case the cause of asthma was some endocrine dysfunction; the blood pressure in this case was 78 systolic and 55 diastolic and the attacks were mostly associated with the monthly periods. In one case there was a white cell count of 75,000 per c.cm. with an eosinophilia of 85 per cent. The high eosinophilia tends to show that in this case the main cause of the asthma was some undetermined allergic factor. In one case the main symptom was sneezing.

The consideration of these points throws some light on the causes of the failure of response in the Arneth count and in the improvement of the patients' condition. These causes may thus be summarized as follows:—

- (1) Some serious underlying disease such as tuberculosis.
- (2) Bronchial sepsis only superadded, in a case of true allergic asthma.
- (3) The absence of any bronchial factor.
- (4) The bronchial factor being present but being unaffected by the vaccine treatment.

Summary

- (1) The Arneth counts in 25 cases of asthma before and after treatment with auto-vaccine from the sputum have been presented.
- (2) The counts showed a marked shift to the left before treatment in all the cases.
- (3) After the treatment this shift was reduced in the cases favourably affected by the treatment.
- (4) It is suggested that marked improvement in the Arneth count after treatment with the vaccine is a good prognostic sign.

1935; the provisional diagnosis was nephritis with secondary cardiac complications.

He complained of anæmia, palpitation, breathlessness, weakness and swelling of the legs.

He was found to have a systolic murmur at the pulmonary area, heard also at the apex, but not conducted into the axilla. His face was puffy and he had marked œdema of the feet and ankles; neither spleen nor liver was enlarged. He had no albumin in his urine. He had an intermittent temperature rising to 100°F. in the afternoon each day, later it rose higher—up to 104°F. for two days—and became remittent; his pulse was usually about 90 per minute but later, when the temperature went higher, it rose to 110.

HEMATOLOGICAL FINDINGS

Hæmoglobin—2.47 grammes per 100 c.cm. of blood (i.e., 18 per cent of 13.75 grammes).

Red cell count—1,880,000 per c.mm.

Reticulocytes—3.6 per cent.

Leucocytes—2,650 per c.mm.

Polymorphonuclears—68 per cent.

Lymphocytes—26 per cent.

Large mononuclears—5 per cent.

Eosinophiles—1 per cent.

Cell volume—14.2 per cent.

Mean corpuscular hæmoglobin—13.14 $\gamma\gamma$ (normal = 28).

Mean corpuscular volume—75.53 cu. μ (normal = 90).

Mean corpuscular hæmoglobin content—17.40 per cent (normal = 31).

Colour index—0.47.

Volume index—0.84.

Van den Bergh tests—direct and indirect both negative.

Urobilin—distinct in undiluted urine.

Gastric analysis.—Definite hypochlorhydria. Free hydrochloric acid, except for a trace at half an hour, in two samples only, after 1 and 1½ hours; the highest was 12 c.cm. of N/10 HCl in the latter sample.

Wassermann reaction—'slightly positive'.

Stools for helminths—600 hookworm ova per gramme of stool.

Other examinations.—Repeated bacteriological and protozoological examinations of the stools, and blood examinations for malaria parasites were 'negative'. The serum agglutination test for enteric and other organisms, the aldehyde and the antimony test, and a blood culture for leishmania were all negative.

Diagnosis.—Simple hypochlorhydric anæmia.

The patient was on an iron-poor diet, his absorption was defective, and his anæmia was probably increased slightly by a low-grade hookworm infection.

Treatment.—Quinine sulphate 20 grains a day for 7 days had no effect on his fever. He was given no treatment for the hookworm infection at this stage.

On 4th November, he was put on to ferrous sulphate tablets, six grains three times a day, and half a drachm of dilute hydrochloric acid twice a day. The iron was given for 26 days, but the hydrochloric acid was continued throughout his stay in hospital.

Progress

Date		Reticulo- cytes, per cent	Hæmo- globin, grammes per 100 c.cm.
29-10-35	Before treatment	3.6	2.47
9-11-35	After 5 days	21.0	..
13-11-35	" 9 "	14.0	..
14-11-35	" 10 "	15.1	5.77
19-11-35	" 15 "	5.9	..
21-11-35	" 17 "	4.2	..
23-11-35	" 19 "	4.6	..
26-11-35	" 22 "	3.5	10.31
19-12-35	" 45 "	0.7	11.41
4-1-36	" 61 "	0.8	10.45

Temperature.—After 10 days of iron treatment the temperature began to fall and on the 22nd it reached normal.

Epileptiform seizures

On 30th November after the patient had had iron for 26 days, that is to say $6 \times 3 \times 26 = 468$ grains of ferrous sulphate, he had a fit at six o'clock one morning; when seen by the house physician he had recovered but had twitchings of the muscles of the face and was drowsy.

At 7-30 he had another fit; he had clonic spasms of the muscles of his neck, face, arms and legs; he bit his tongue. He became completely unconscious and the corneal reflex was lost. The fit lasted about five minutes. This was followed by a third similar fit at 9-15. I saw him in another fit at about 10-15 whilst doing my round of the wards. He had been speaking to me just before and complained of severe headache ever since the first fit; he was not able to describe any aura; the fit came on suddenly whilst he was lying in bed; this fit lasted longer—about 20 minutes. During the day he had three more fits of apparently increasing severity and after the last he seemed exhausted, his pulse was irregular and bounding, he had some congestion of the lungs, and he was cyanosed. He was given oxygen for 15 minutes and a strophanthin injection.

A lumbar puncture was done by Dr. Chaudhuri; the fluid was found to be under slight pressure but was otherwise normal; there was no increase of the cellular elements and it was sterile on culture. The iron administration was of course discontinued.

On the following day he was quite normal except that he had a slight headache which persisted for a few days.

His temperature rose to 101°F. on the days he had the fits, but on the next two days was 99°F. and then it fell to normal again. A potassium bromide mixture was given for three days only.

On 16th December he was given tetrachlor-ethylene 4 c.cm., and oil of chenopodium 1 c.cm., for the hookworm infection. Later, stool examinations showed no ova present.

As his blood hæmoglobin showed a tendency to fall he was again put on to iron; ferrous sulphate was given in smaller doses, grains 3 thrice daily. His further progress was as follows:—

Date	Days of second iron treatment	Reticulo- cytes, per cent	Hæmoglobin, grammes per 100 c.cm. blood
4-1-36	..	0.8	10.45
13-1-36	5	1.7	..
15-1-36	7	2.0	..
18-1-36	10	0.2	14.02
27-1-36	19	..	15.95

On 27th January his blood count was as follows:—

Hæmoglobin—15.95 grammes.

Red cells—6,000,000 per c.mm.

Cell volume—53.4 per cent.

Mean corpuscular hæmoglobin—26.58 $\gamma\gamma$.

Mean corpuscular volume—89.00 cu. μ .

Mean corpuscular hæmoglobin concentration—29.87 per cent.

Colour index—0.95.

Volume index—0.99.

Fractional gastric analyses (alcohol)

30th Jan.	16.00	0	0	6	8	10	14	2	8	10	10

Weight.—The patient weighed 86½ lbs. on admission but he had œdema. His weight fell to 82¼ on 26th November. His weight had increased to 95 lbs. by 19th January.

Discussion

The patient gave no history of ever having had epileptic fits before; he has had none since. He gives no history of head injury and shows no evidence of any such injury.

The dose of iron that he was receiving was a big one; the pharmacopœial dose of ferrous sulphate is 3 grains, but we have given 27 grains a day to tea-garden coolies without any ill-effects, a total of 522 grains in a period of three weeks. He was, however, a small man—making allowance for the œdema—only about 80 lbs.

About a year ago another case of fits following the administration of large doses of iron occurred in this hospital. This was a woman who had had 12 grains of ferrous ammonium sulphate a day for 33 days; she had a strongly positive Wassermann reaction, and for this reason no special note was taken of this case at the time.

Hurst (1934) reports a case of encephalopathy following the administration of 40 grains of iron

and ammonium citrate four times a day for 21 days; on the other hand Witts (1933) has given as much as 300 grains a day without ill-effects.

This patient also had 'slight positive' Wassermann reaction, but gives no history of syphilis and has no stigmata. In both cases there was some serological evidence of syphilis and it seems just possible that such patients are more susceptible than the normal to large doses of iron.

Amongst normal individuals the degree of susceptibility to any drug is always a variable factor, and it is possible that this dose of 468 grains ($6 \times 3 \times 26$) in a period of 26 days to a man weighing only 80 lbs. is one that will produce symptoms in the exceptional individual. Further, it is probably an unnecessarily large dosage, or at least one that need not be continued for so long, and we have now made a rule to continue this dosage for not more than three weeks at a time.

Hurst (*loc. cit.*) said that his patient 'almost died' after 3,360 grains of iron and ammonium citrate in three weeks; this represents a smaller amount of utilizable iron, according to the figures quoted by Witts (1936). I do not, however, know how near to death my patient was, nor was Hurst explicit regarding his mensural technique. Although the symptoms were extremely alarming, on the following day the patient was little worse for the attack.

From other points of view this case is more instructive than remarkable.

The diagnosis.—There was much excuse for the original clinical diagnosis, though it was obvious that there was a greater degree of anæmia than is usually produced by either heart disease or kidney disease alone.

In this country the clinical picture is nearly always obscured by a multiplicity of helminthic and protozoal infections, but on more careful examination supported by clinical laboratory findings it became obvious that an anæmia of a microcytic type was the most important defect.

The fever.—This was low at first, rising only to about 100°F. , and did not attract any particular attention, as such a degree of fever is common in extreme anæmia, but later it rose to 102°F. daily, and, as no cause for it was found after repeated blood examinations, quinine was given in adequate doses for seven days as a therapeutic test. As this had no effect on the fever a blood culture for leishmania was done; this also was negative. The disappearance of the fever with the anæmia and the failure to find any other cause for it during the patient's stay in hospital—about three months—does seem to indicate strongly that the two conditions were closely associated, and that the fever was secondary to the anæmia.

The hypochlorhydria.—A low gastric acidity is often found in cases of severe anæmia, but

(Continued at foot of next column)

INJURIES OF THE SKULL

By HENRY SMITH

LIEUTENANT-COLONEL, I.M.S. (Retd.)

Blenheim, Main Road, Sidcup, England

AFTER two and a half years in India my first case of injury of the skull was sent in to me.

The man had fallen from the top of a bridge pier, about 60 feet high, into a dry river bed near Quetta. He was unconscious, there was no sign of injury on the scalp or anywhere else

(Continued from previous column)

it is not a constant finding as has been suggested by Apperly (1936), and we have a patient in hospital at present with only 2.75 grammes of hæmoglobin per 100 c.cm. of blood, and hyperchlorhydria. It is not possible to say which is primary, the anæmia or the lowered gastric acidity, in many cases of anæmia associated with achlorhydria or hypochlorhydria. In this case, there seems little doubt that the poor gastric acid secretion was primary and that possibly the defect was exaggerated slightly by the anæmia. Even after a sixfold increase in hæmoglobin the maximum acidity only increased from 12 to 14 c.cm. N/10 hydrochloric acid.

The reticulocyte response.—This was in every way characteristic. In cases in which the hæmopoietic tissue is functioning properly, there is always some degree of reticulocytosis when the hæmoglobin is as low as it was in this case. At the first examination it was 3.6 per cent; there was a sharp rise, 21 per cent, on the fifth day of iron administration and then a steady fall, the original level being reached about the twenty-second day. When the second course of iron was given there was practically no reticulocyte response. This again is what one would expect, as, provided the dosage of the deficient factor—iron in this instance—is maximal, the response is always in proportion to original level of hæmoglobin. It will be noted, however, that the actual rate of hæmoglobin regeneration was more rapid during the second course than during the first, as in the first the hæmoglobin improved by 3.3 grammes in ten days against 3.57 grammes in the second in the same number of days. This shows that the reticulocyte response *per se* is not an indication of the rate of blood regeneration; this is a generally recognized fact.

The hookworm infection.—It is obvious that the hookworm infection had little depressing effect on the blood regeneration, and, although there was a slowing up of the regenerative progress, the slight tendency to regression in the hæmoglobin percentage was noticeable only after the worms had been removed.

except that he had a large retropharyngeal effusion of some sort sufficient to threaten respiratory obstruction. He had evidently come down on the crown of his head and had a fracture of the skull presumably from one jugular foramen to the other which led to the retropharyngeal effusion.

I instructed the attendant to send for me at once if respiratory trouble set in—I lived a few minutes' walk from the hospital—an hour or so later consciousness was returning definitely so I presumed that there was no fracture of the vertex and no pressure on the cerebral cortex. The effusion did not increase and soon began to diminish so that it was not necessary to do anything beyond nursing. He rapidly recovered and was able to resume work after three months as a mason's attendant, but he did not like pier masonry.

Standard teaching is that fractures of the base of the skull are very much more fatal than fractures of the vertex. This doctrine should be altered as the reverse is the case but it is always difficult to get a doctrine, which is based on tradition, altered. This was the severest type of fracture of the base and yet he made a rapid and perfect recovery.

The next case came into hospital unconscious from a blow of a beetle on the head, though there was no wound on the scalp and no x-rays in those days. I assumed that there was a fracture of the vertex and extra-dural hæmorrhage. It was a medico-legal case. I exposed a fissure in the temporo-parietal region, I took out a full-sized trephine disc and scraped and washed out the clot, as I thought, thoroughly. He did not recover consciousness and died. I did a post-mortem examination and was surprised to find that I had left most of the clot behind and I had only scraped furrows in it. I had to appear in court of course, and I discovered that these clots adhered to the skull and dura mater with great tenacity—so much so that scrapers and spoons used through a trephine hole are practically useless in the area beyond the width of the trephine opening. Clots of this kind usually cover an area three inches or more in diameter. I decided to use my naked index finger and finger nail on the next case instead of spoons and scrapers. I had plenty of them as I was having up to 150 medico-legal post-mortem examinations in the year—twenty-five years at Jullunder and Amritsar; a considerable proportion of these were skull injuries. In the next similar case I took out a disc of bone and enlarged the opening to let in my index finger full length easily, and found my finger nail an ideal weapon guided by the feeling of the finger tip. I continued the use of this simple 'weapon' and from that case on I rarely had a death from extra-dural hæmorrhage.

Another case of interest was a man who had got a blow of a beetle over the centre of the

crown. He was unconscious. He had no scalp wound, but a little effusion beneath the scalp which indicated where the blow had been struck. I made an antero-posterior cut across the site of injury; this exposed a transverse fracture which I followed from ear to ear. I cut a trench the full length from ear to ear wide enough to admit my index finger and scraped out the clot, being careful to get the whole of it out. I then caught him by the forehead with one hand and the occiput on the other to test if the fracture had gone further. The front and rear halves of the skull moved freely independently of one another. I put a few stitches in the scalp wound in the middle, and put on a dressing. A few hours later consciousness was returning and was quite returned next morning. When I finished there was a cavity which the clot had occupied which would be of cubic capacity of four to five ounces of fluid. I stitched up the wound completely without a drain as there was no oozing. About a month later he appeared in the witness box to give evidence against his assailant. I was present as a medico-legal witness and heard him stand a cross examination, which he did well. I saw him a year afterwards and he was quite well. This was as severe a fissured fracture of the vertex and of the base, as anyone is ever likely to come across. The clot on the vertex was properly removed and the fracture of the base was left to take care of itself.

Contrecoup.—A case of interest was a boy of sixteen; he was brought into hospital unconscious; he had got a blow on the temporo-parietal region of one side of the head. I cut down there in search of a fracture; there was none. I took out a disc in that region; there was no hæmorrhage there. I exposed the opposite side of the skull; there was no fracture there. Nevertheless I took out a trephine disc and discovered a large clot which I removed and the patient did well; the only explanation I can give is that the skull had enough of the elasticity of youth to stand the strain without fracturing but that the concussion alone was sufficient to detach a small portion of the dura mater which very soon became large. This case shows how easy it is to detach the dura mater from the vertex of the skull. Fractures with hæmorrhage between the dura mater and the skull commencing just under the fracture and thus rupturing more and more of the thin-walled arterioles going from the dura mater to the inner table of the skull. The speed of this dislocation will depend on the size of the vessels ruptured as the larger ones have a higher blood pressure than the smaller ones and hence unconsciousness sets in sooner in fractures of the temporal region than elsewhere.

In the many cases (post-mortem and ante-mortem) that I have seen, a striking fact was that the blood clots beneath fractures of the vertex are always uniform in size. The reason

for this is evident. The blood pressure of these effusions is higher than the pressure of the cerebro-spinal fluid, and hence, the brain tissue being mouldable, the cerebro-spinal fluid is driven out of the skull into the spinal canal.

The blood pressure in these clots, considering the size of the vessels ruptured, I should think seldom exceeds 30—40 mm. Hg., so that it is not sufficient to rupture or lacerate the brain or do irreparable damage to it; the cubic capacity of the cerebro-spinal fluid is thus the maximum size possible of the clot underneath fractures of the vertex and is the explanation of the fact that such clots are so uniform in size.

Fractures of the base.—Of these I have seen many; in some the bleeding is into the nose, in some it is retranasal, in some retropharyngeal and in some from the ears. The retropharyngeal ones are much fewer in number than the others. I have seen cases in the post-mortem room in which fractures of the vertex not infrequently radiated into the base, the radiations only being exposed when the dura mater was stripped off the floor of the skull. The cases of fracture of the base which came before me clinically, diagnosed by bleeding from the regions above, noted following severe violence, when not complicated by fractures of the vertex, as indicated by persistent unconsciousness (the symptoms of hæmorrhagic pressure between the dura mater and the skull), do well when not interfered with. They may be unconscious for a short time immediately following the violence, but usually recover, well within an hour. If unconsciousness lasts more than that time fracture of the vertex and extra-dural hæmorrhage should be suspected and explored for.

How is this to be explained by the schools? I never saw a case in which the dura mater of the base was dislocated and flooded up by hæmorrhage without which pressure on the brain on that region is impossible. This will be evident to any one who, in doing a post-mortem, extracts the dura mater from the floor of the skull as should always be done in medico-legal post-mortems in case of injury to the skull. The dura mater is so firmly fixed to the floor of the skull that much higher pressure than the available arterial pressure would be required to dislocate it, and hence in practice it never occurs.

The dura mater of the vertex is very easily torn out and hence it is so generally dislocated by the trifling arterial pressure available from the few ruptured arterioles beneath the fracture. This little pressure is sufficient to rupture other adjacent arterioles and so it goes on until the cerebro-spinal fluid is expelled, when it stops of necessity. Even when the clot is at its maximum the pressure through the dura mater is trifling and not sufficient to do damage to the brain. *I presume the absence of the cerebro-spinal fluid has most to do with the unconsciousness and abeyance of other functions of the*

brain, leading to death. After removal of these extra-dural clots, as the cerebro-spinal fluid becomes re-established, consciousness returns.

In practice an injury of the skull followed by unconsciousness comes first before a general practitioner. He sends the case to the nearest hospital where the surgeon takes charge. Public sentiment obliges him to do so, however capable he himself may be. He has no more to do with it; the hospital authorities will not allow him to have anything to do with it. Public sentiment is very wrong in this attitude as time is a grave consideration in these cases apart from the fact that the general practitioner should be just as competent to operate on these cases as the hospital surgeon. The general practitioner who feels competent to operate on these cases should do so in the patient's house or in a nursing home; in any case he should insist on being considered in connection with the treatment of the case. The operation is one of the simplest in surgery. The operation does not need an assistant, the patient is unconscious and does not need an anæsthetic and as far as instruments are concerned he can get an inch gouge and a small carpenter's chisel in any local hardware shop. All he needs in addition to these is a needle and thread, a mallet, a scalpel, and his own index finger. The gouge will bore the hole in the skull as well as a trephine, he can enlarge it and trim the edges with a small chisel. The indications for exploring are clear, if the operator finds no hæmorrhage there is no harm whatever done. The patient is to die anyhow and exploring will not shorten his life by one minute, but he will rarely fail to find hæmorrhage beneath the fracture of the vertex.

I hold that it is the imperative duty of the surgeon to explore for hæmorrhage beneath fractures of the vertex with unconsciousness lasting an hour as the outside limit. In cases in which unconsciousness sets in a few minutes after the injury, he should explore at once as this unconsciousness is not due to shock which sets in at once.

Those who wait with unconsciousness for something favourable to turn up will find that it is a funeral which turns up almost invariably.

Splinters of bone driven through the dura mater into the brain, we occasionally come across, from a heavy blow of a semi-sharp weapon. There is a free outlet for blood in such cases, hence they should be treated by ordinary surgical principles.

Apart from these splintered cases hæmorrhage into the pia arachnoid hardly ever occurs. In splintered cases in which the splinter cuts through the dura mater there may be a mere trace of hæmorrhage in the pia arachnoid, but so little that it is of no practical importance and can safely be left there. In fact it is so attached to the membranes that the insignificant film could not be removed.

This paper is based on the personal experience of a wealth of material such as has not been surpassed by that of any man hence I do not pad it up with reports of cases but give my conclusions after careful considerations of that experience as a whole; neither do I quote authorities. I go my own way uninfluenced by any authority.

[*Note*.—The writer of this paper has a world-wide reputation as an ophthalmic surgeon and he can rightly claim that much of his success was due to the originality of his methods. Nevertheless, we feel that we cannot pass the last sentence of his paper without some protest.

If the principle by which Colonel Smith appears to be guided were universally accepted and followed to its eventual conclusions, medical—including surgical—science would cease to advance. Surely, no one can afford to be guided *only* by his own experience—even if that experience is so vast that he can boast that it 'has not been surpassed by that of any man'. In these days when the daily toll of the roads is mounting so rapidly in every civilized country, there must be many other surgeons whose experience justifies the drawing of 'conclusions after considerations of that experience as a whole'. In our experience of the literature of head injury, the majority of these 'conclusions' differ materially from those of Colonel Smith.

There are many points on which Colonel Smith's opinions are unorthodox. To mention two only—we cannot agree that, when expert surgical assistance is within reasonable call, a practitioner with little experience should undertake immediate operation in unsuitable surroundings with instruments not designed for the purpose, nor do we consider the unsterilizable finger nail a legitimate weapon for brain surgery.

We append a short note on head injuries kindly contributed at our request.—EDITOR, *I. M. G.*

NOTES ON HEAD INJURIES

The gravity of head injuries depends chiefly on the extent of damage, sustained by the intracranial structures. A careful neurological investigation becomes, therefore, a necessity, not only from an academic point of view but from that of treatment. Skiagraphy is indispensable in every case and the advantages of lumbar puncture, both diagnostic and therapeutic, are too evident to require any emphasis.

It is customary to divide injuries of the skull into simple and compound fractures and again into fractures of the vault and of the base, although these conditions may be associated. The dura mater, being firmly adherent to the base of the skull, is more easily torn in the case of basal fractures. Under injuries of the brain, may be included cerebral concussion, compression and laceration, but these conditions are usually coexistent. Extra-dural arterial hæmorrhage is commonly of middle meningeal origin and the bleeding vessel can be secured without difficulty. Cortical veins are very thin and fragile and may easily rupture, giving rise to extravasation of blood and formation of a subdural hæmatoma. In such a case, the symptoms are latent for a time after the injury.

The indications for operative treatment in the case of head injuries are definite, and operative procedure should not be undertaken in a spirit of levity; it is imperative that asepsis and

hæmostasis are ensured in every case. The immediate indications for operation may be briefly enumerated here:

(i) Elimination of infection—wounds of the scalp may be excised and compound fractures rendered surgically clean.

(ii) Control of hæmorrhage—from the scalp, diploë and intra-cranial structures.

(iii) Relief of pressure symptoms—cerebral compression of recent duration may be due to depressed fracture, extravasated blood, traumatic œdema and foreign bodies.

Owing to the increase of road accidents, head injuries are becoming more frequent in emergency surgery. The most serious complications are due to injuries to the cranial contents. In the absence of complications, it is the experience of most surgeons that no untoward results follow in the majority of cases, in which conservative treatment is adopted. Post-traumatic cerebral complications and sequelæ present a different problem for the neurologist and for the surgeon. In reality, the subject of head injuries is an extremely difficult one. The aphorism of Hippocrates that 'no head injury is so trivial as to be ignored or so serious as to be despaired of' may be remembered with humility.

MULTIPLE PARALYSIS FOLLOWING MEASLES

By NUR MOHAMMAD, M.S.M.F.

Sub-Assistant Surgeon, In-charge Sahiwal Dispensary,
Shahpur District, Punjab

B., a female child, aged 4 years, was attended by me in February 1935. She had a temperature of 104°F., sore throat, running from the nose and conjunctivitis for the last two days. On the fourth day of the disease, she developed the typical rash of measles all over the body and Koplik's spots inside the mouth. On the seventh day, she developed broncho-pneumonia of the right lung, followed by similar signs the next day in the left lung. The case was treated on usual lines and passed on to convalescence after four weeks.

Her temperature came down and she started moving about. In the eighth week when the child was progressing well, the mother noticed one morning that it had difficulty in walking and fluids passed through the nose instead of being swallowed. There was also some dyspnoea. I was again called to see the girl and found that both the legs were paralysed. Paralysis being that of the lower neuron type. There was paralysis of the soft palate and weakness in the movements of the chest, probably due to defective function of the diaphragm. The case was treated with iodides, nux vomica and electricity and was cured in two months.

Paralysis following measles is a rare occurrence so it was considered worth while publishing this report.

Indian Medical Gazette

MARCH

NUTRITION REQUIREMENTS

We print elsewhere part of a report on 'The Physiological Bases of Nutrition' recently published by the League of Nations Health Organization. In September 1935 the Second Committee of the Assembly devoted three days to a discussion of nutrition in relation to public health, agriculture, and economics. The most important conclusions which emerged may be summarized as follows:—A general increase in the consumption of the more nutritious food-stuffs would raise health standards and at the same time stimulate agricultural production; this in turn would have a beneficial effect on world trade and hasten economic recovery. The problem of increasing consumption was delegated to a 'mixed committee', including agricultural, economic, and nutrition experts, which was to meet in February 1936. In order to provide a solid basis for this committee to work on, it was necessary to define as exactly as possible, in the light of modern knowledge, the nutritive requirements of human beings. This is what the present report, drawn up by a number of leading nutrition workers from England, the United States, France, Sweden and Russia, attempts to do. Its conclusions will be laid before the 'mixed committee'.

The dietary standard adopted is, qualitatively speaking, a high one. The value of the 'protective' foods—'milk and milk-products, eggs, glandular tissues' and 'green leafy vegetables, fruit, fat, fish, and meat (muscle)'—is emphasized throughout. In the various tables one finds a novel method of laying out diet schedules; the 'protective' foods, yielding a proportion of the total energy requirements, are grouped together and the amounts of each specified, while the remainder of the diet can be made up from cereals, fats, and sugar as needed. This means, in effect: 'first eat what you should; then you can eat what you like'. One litre of milk per

day is recommended for pregnant and nursing mothers, and for growing children; this seems a high figure, but there is no question of 'stuffing' involved. The 'protective' foods, abundantly present, replace some of the cereal foods which at present figure over-prominently in average diets. The standard of calorie intake suggested—2,400 net per day for an adult being, in ordinary everyday life, in a temperate climate and not engaged in manual work—cannot be considered excessive.

Another new departure, conforming with the general trend of modern dietetics, may be noted; the emphasis is on foods rather than on food factors. The modern nutrition worker, in assessing the value of a diet, has learnt to think in terms of the foods it contains without making preliminary calculations of its protein fat, mineral, and vitamin content.

The report recommends a type of diet which is better than, but does not radically differ from, the ordinary diets of Western civilization. It provides the necessary foundation for agricultural, economic, and public health nutrition policies in Europe, North America, Australia, New Zealand, etc. But as far as the East is concerned, a different approach will be necessary.

It would be at present absurd to adopt so high a standard of dietary requirements in such countries as India, Malaya and China—as absurd as to suggest the introduction of tiled bathrooms into Indian villages. The nutrition worker in the East must adopt a far lower standard, a standard which does not and cannot represent the *optimum*, but nevertheless represents a decided improvement on existing habits. He can aim at a little more milk, more green vegetables and fruits, the partial replacement of cereals by legumes such as soya bean, the greater use of unmilled cereals, and so on. Granted these limitations, there is no reason why Eastern dietary standards should not be defined and used for the same purposes as those for which it is hoped the report under discussion will be used. When a little more data has been collected, the League of Nations might well convene an Eastern Commission on Nutrition to lay down minimum dietary standards in terms of Eastern habits and foodstuffs.

THE RADIO-ACTIVITY OF THE THERMAL SPRINGS OF RAJGIR

By N. K. CHATTERJI, B.Sc.

Assistant Analyst, Bengal Public Health Laboratory

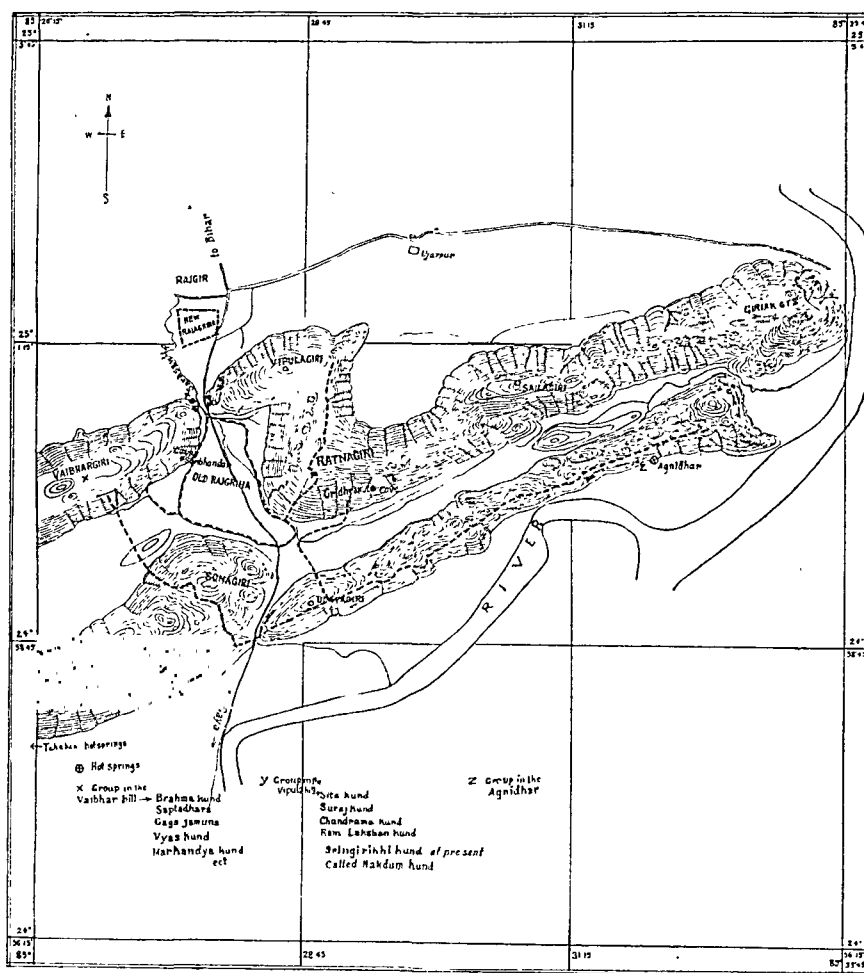

THERE are spas and health resorts all over the world where invalids and people with chronic illness flock in great numbers every year. The special importance of these places

general. Whatever may be the cause of their alleged healing power it is beyond doubt that most people derive immense benefit from a sojourn to these places and considering the general state of health in India any natural therapeutic agent would be welcome.

With a view to exploring the possibilities of the thermal waters of Bengal and the neighbouring provinces for therapeutic purposes I took up in detail the investigation of the springs in and around Rajgir.

A short description of Rajgir with the topographical map (map I) should be of some interest in view of its historical importance. Rajgir is

MAP I

Rajgir with its hills to Giriak.

lies in their springs, which are usually hot and hold in solution large quantities of mineral organic and gaseous matters to which for centuries their healing power has been ascribed. The modern view, however, tends to attribute the beneficial effects of these places to change of environment, rest, disciplined exercise, diet and habits of life, rather than to any special therapeutic power of the water of the spring. Some of these springs contain radio-active elements which, combined with a hot bath, have probably a stimulating effect on metabolism in

now a small village (population 2,700), 14 miles south-west of Bihar subdivisional town of Patna district. Historically, archaeologically and religiously, Rajgir is one of the most important places in India, being the prehistoric capital of Jarasandha and at one time the royal residence of Bimbisara, Ajatsatru and Udayan. Lord Buddha first studied and after attaining Buddhahood used to live there in retreat and often preached and taught his disciples. There are many Jain temples on the hills which are associated with the memory of Lord Mahabir

and his disciples. The old city was surrounded by five hills, namely, Vaibhar, Vipula, Ratna, Uday and Sonagiri. Fa Hien and Hiuen Tsang, two Chinese travellers, mentioned Rajgriha with Tapata (hot stream) in their account of this district. At the foot of the mount Vaibhar runs the Saraswati river and there are stream water reservoirs on the west, as well as on the east bank of it. The spring water reservoir at

Experimental

The study of these thermal springs was conducted in the following manner:—

I. Spot analyses (done *in situ*) were made of the radio-activity and of the gaseous contents, the physical characters of the different spring waters being noted. The radio-activity was estimated by using Prof. Schmidt's electrometer. The results are summarized in table I.

TABLE I

Name	Tempera- ture, °C.	PARTS PER 100,000		RADIO-ACTIVITY		PHYSICAL	
		Free CO ₂	Dissolved oxygen	Gaseous emanation in M. U.*	Per litre in M. U.*	Colour	.. Odour

$$* [M. U. (Maché unit) = \frac{1}{3,000,000} \text{ millicurie}]$$

the foot of the Vaibhar hill has seven outlets whereas the spring water reservoir at the foot of the Vipulagiri has only six, most of which find their way into the said Saraswati river. These springs are shown in map I. Rajgir still enjoys a reputation as a place of popular Hindu pilgrimage and a health resort in winter. Our study of these springs was carried out in the following manner.

Geological observations

The Rajgiri hills consisting of slaty schists and quartzites are less metamorphosed (map II). The locality is situated beside the rich mica-bearing belt of Bihar. In fact, the south-west corner of Gaya district (close to Rajgiri) forms part of the mica-producing area which coincides with a great belt of schists and associated gneissose granite, some 12 miles broad and 50 miles long stretching from Hazaribagh through the south of Nawada subdivision into Monghyr. Hence the mica-bearing ores are one of the prominent minerals found in the southern, eastern and western neighbourhood.

In this table important springs which are commonly used are included, all of which are typical ones of the locality. In addition to these a local surface well and the river Saraswati are also included for comparative study. Spring waters are more or less radio-active and thermal, and, as they come from a great depth, these waters can be considered to be reasonably free from surface contamination. The river Saraswati though partially fed by the outflow water of these springs shows little radio-activity. As the units of radio-activity M. U. (Maché unit) are not higher than ten except for the gas, their radio-activity is to be considered weak.

II. Samples were brought to the laboratory without delay for complete mineral analysis. Table II will show the mineral contents of this radio-active thermal spring.

These samples were collected and analysed in the month of October. The total solid matter in solution was very small, ranging between 4 to 6 parts per 100,000, and the nature of the minerals was similar. The greater portion of their contents is in all probability mica (Al₂O₃, SiO₂.Mg) in solution as its characteristic sheen

the Singar mica mines in Gaya district. These springs therefore are not superficial, but, coming from a distance, derive their radio-activity by passing through this kind of ore. Again it is a well-known fact that the greater number of hot springs in all parts of the world are found in volcanic mountainous districts. Notwithstanding the fact that outbreaks may not have occurred for centuries, evidence of their former activities may be observed by the presence of old craters, lava-beds and rugged corrugations. In volcanic areas elsewhere, less violent, secondary phenomena, such as hot springs, geysers and fumaroles emitting smoke, give evidence of activity beneath. As regards the possible existence of previous volcanic activity, we have the account of Chinese travellers that there was a mountain emitting thick volumes of smoke darkening the sky above, which was seen even from the then capital of Magadh kingdom (modern Bihar).

At the present time these springs are in an unhygienic condition and it is suggested that, as in other countries, the Government or a public utility body might take over their administration as a going concern for the benefit of the community.

I wish to express my thanks to Lieut.-Col. A. D. Stewart, C.I.E., for his help and advice and for permission to use Prof. Schmidt's electrometer from the Institute of Hygiene and Public Health, Calcutta, for the spot analysis. Also my thanks are due to Dr. B. B. Brahmachari who gave me some facilities for conducting the investigation as well as to Prof. H. Ellis C. Wilson and Dr. Bashir Ahmed for their help and suggestions.

I desire to thank Dr. A. K. Sen, Director of the Bengal Public Health Laboratories, Calcutta, for permission to publish this paper.

THE MIDDLE-AGED PATIENT, AND LATER

(A LECTURE TO POST-GRADUATES)

By G. T. BURKE, M.D., F.R.C.P. (Lond.)
LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine, Lucknow University.

I HAVE chosen this subject, not only in order to bring before us those ailments from which the patient of 40 and over is especially prone to suffer, but also in order to emphasize the importance of arresting, so far as possible, in the younger patient those processes, many of them degenerative, which may lead to the results which we so often find ourselves unable to alleviate.

Middle age should find the individual at the summit of his mental powers, and still not far past that of his physical attainments: how long he will remain at this level depends to the greatest degree on how he has developed and treated himself during his earlier years, and to a much less extent on the sort of tissues he has inherited from his forebears. The decline into old age should be a very gradual one, and not a steep descent.

Age is a question of the individual, who may be an old man of forty, or a young man of sixty or older: it is useful, thus, to know how old the patient actually is, that we may judge how far his condition is likely to be pathological. 'A man is as old as his arteries' sounds a trite saying, but it is a true one if for 'arteries' is read tissues generally. I have been amused by the student who, having described his first patient as 'an old man of forty', when he has realized his teacher's age gives his description of the next as 'a young man of fifty'!

An important point to realize about the elderly patient is that there is a general blunting and slowing down of reactions: pain may be much less obvious; the pulse not accelerate to such a degree with fever; the fever itself not be appreciated so much, and perhaps require to be taken in the rectum for any degree of accuracy; the bowels act less well and yet constipation does not cause the harm it does in the young. Chronicity is the general rule in the affections of old age.

Leonard Williams points out that, while the assimilation of an adequate diet is most important in the period of growth and development, during the later years of life it is output or katabolism that is most essential. We can realize this in the many cases of inadequate kidney function due to degenerative changes which we meet with in late middle and old age. Intake and assimilation are of relatively less importance, and it is a mistake unduly to urge on the old a diet with which they feel they cannot deal. It is not what is eaten but what is digested which counts, and the elderly relative who needs 'supporting' in the opinion of his anxious women-folk is often supported out of

the world altogether! As the individual passes towards the stage of the 'lean and slippered pantaloons' he needs a closer approximation to the diet of the 'puling infant', in which guise he entered on the stage of this world. The quantity as well as the quality of the food should be cut down, and milk, fruit, fresh vegetables, and eggs take the place of the stimulating diet, meat and spices, of former years. It is not only the aged who need this caution, for the majority of men over the age of forty eat much more than they require, and it is true that a great many individuals dig their graves with their teeth. It is within the experience of many of us that members of long-lived families are usually small eaters, and also that small eaters tend to be more active. In this country the overeating is usually of carbohydrates, and results in the high proportion of glycosurics which is met with, and which complicates the treatment of the other maladies of late life.

The digestive system is the site of disorder not infrequently after middle age. Gastro-duodenal ulcers are liable to occur, and there is the constant possibility of malignancy to be thought of. Beware of an intractable diarrhoea in an old person; it may signify the presence of a 'new growth', or it may be the expression of nature's attempt to compensate for renal inadequacy and to stave off uræmia. A chronic colitis is another cause for diarrhoea which, however, is not confined to those past middle age: examination of the stools is of course called for, and careful palpation of the abdomen for evidence of contracted or dilated colon, while a rectal examination, with proctoscopy if necessary, may show ulcerative colitis or the existence of a new growth in the pelvic colon or rectum. Cancer of the colon may cause either diarrhoea or constipation, and the development of either, in an individual approaching or past middle age, should lead to a most careful survey of the patient generally. Blood may be present—it usually is obvious in cancer of the lower part of the large bowel—but may be 'occult' and require the guaiac test to demonstrate it. If you wait for severe colic and visible peristalsis, or for actual obstruction, the opportunity for successful treatment may have gone, and emaciation, also, will point a poor prognosis. Of the use of x-rays in diagnosis I need lay no emphasis; it is often of the greatest importance. Fortunately involvement of glands and secondary deposits in other organs usually occur fairly late, and success frequently follows removal of the growth.

Renal inadequacy as a cause for diarrhoea I have also mentioned; this is only one of the symptoms for which a sufferer from this condition may consult his doctor. Chronic Bright's disease has various warning signals, and disregard of them can only lead to disaster. Of these danger signals a chronic diarrhoea is one; another is headache—a protean and too often

disregarded symptom, especially as minor degrees of hypermetropia or hypermetropic astigmatism may cause headache as presbyopia gradually approaches. The headache may only be felt on rising in the morning, or may be of any degree of severity; if associated with high blood pressure it may be throbbing in character, and if there is any uræmia there may be drowsiness, nausea or vomiting, and retinal changes. Instead of headache, this patient may complain more of giddiness or fullness and noises in the head.

A third symptom is directly connected with the renal system itself: the patient may complain of nocturnal frequency of micturition. Here we have to differentiate from the frequency of enlargement of the prostate, not usually difficult, for there is no obstruction or delay, and there is polyuria. The patient may come to the physician *via* the ophthalmologist, to whom he has gone for failing vision: the prognosis in his case will be worse in all probability—he will be in better case, however, than the misguided person who visits an oculist for glasses. Attacks of bronchitis, even of 'asthma', or symptoms of cardiac decompensation, may be the reason for consultation, and we have most of us met the diabetic patient who knew that he had glycosuria but who proves to have renal disease as well.

The discovery of early renal inadequacy is a call for a most careful search of the patient for any possible causal factor. Every possible source of infection should be tackled, especially teeth, tonsils, and bowels. Measures to promote activity of the skin include warm bathing and moderate exercise; fresh air must be unstinted, and close and stuffy atmospheres therefore avoided. Diet should be reduced in quantity and in stimulating qualities, nitrogenous foods being cut down, and fresh fruits and green vegetables substituted. An occasional day in bed on water or a milk diet, or longer if the blood pressure is rising, has a good effect, and absence of worry should be insisted on. Measures to promote elimination by the bowel are to be taken, and may include a weekly dose of 'blue pill' at night followed by a saline purge the next morning. Of attempts to lower blood pressure I will only say that, beyond the point at which the kidneys demand pressure for functioning, harm will be done: for continued use of potassium iodide holds a high reputation, as it probably has an eliminating effect also.

I need not consider here the other forms of nephritis, as the patients are too young to come under our present subject.

From the renal system it is an easy step to the cardiovascular, a step taken only too easily by the patients of whom we have been talking. Not by any means all our cardiac patients of middle or later years, however, originate as renal cases: hyperpiesis, arteriosclerosis, syphilis, and cardiac degenerations all contribute

their quota, often in combination. Here it is important to recognize the causes which may be at work. Arteriosclerosis, apart from those cases where it is secondary to kidney disease, and using the term in its widest significance, may result from primary high blood pressure, as occurs in individuals who live hard, eat hard (digging their graves with their teeth, as I have said), or play hard, and who, perhaps, have an inherited tendency to raised pressure; it may be part of a general involution of old age, and as such may occur much earlier in certain individuals; it may be the result of, or be encouraged by certain intoxications, such as lead, gout, and possibly tobacco; or it may follow syphilis.

That high blood pressure is a factor in the production of sclerosis of vessels is evident from its usual absence from the pulmonary vessels, except in those cases where the pulmonary pressure is increased, as in mitral stenosis; and by its particular occurrence at points of strain, such as the arch of the aorta and the orifices of branches. Or the cause and effect may be reversed, and high blood pressure follow sclerosis of the vessels. The typical group of symptoms of arteriosclerosis is the occurrence of giddiness and failing memory in a middle-aged man with thickened arteries, a large heart, and an accentuated aortic second sound; the further symptoms fall into three groups:—renal, of which I need say no more, except that in the primary arteriosclerotic kidney the same degree of polyuria of low specific gravity urine does not occur; cardiac, including fibroid heart, failure, irregularities, angina, and thrombosis; and cerebral, including giddiness, headache, loss of memory, mental changes, transient symptoms from spasm, and cerebral hæmorrhage and thrombosis.

Other symptoms which may arise are due to insufficient blood supply to various parts such as intermittent claudication in the limbs, when exertion causes pain and tingling or even cramps and paresis, with coldness and congestion; or cramp-like pains in the abdomen, to be distinguished from the pains of lead-colic or tabes. In arteriosclerosis the prognosis depends mainly on the condition of the kidneys, for a course has to be steered between the Scylla of renal failure and the Charybdis of vascular rupture or cardiac failure.

Chronic myocardial failure, or degeneration, or the fibroid heart, is essentially dependent on disease of the coronary arteries, and the factors in its production are arteriosclerosis (and its causes), renal disease, age, and syphilis. The commonest symptoms first to call attention are:—shortness of breath, up to cardiac asthma; fainting; cold sweats; headache; loss of memory or mental failure; epigastric distension; cardiac pain; abnormal rhythm. There may be sudden death without any previous symptoms. The signs are correspondingly indefinite, and usually there is arteriosclerosis, cardiac enlargement, a

roughened mitral first sound, and an accentuated aortic second sound: the pulse is often slow and there may be an abnormal rhythm.

Of the symptoms of myocardial failure, the most typical are cardiac asthma and cardiac pain. The 'asthma' consists of attacks of nocturnal dyspnoea, and must be distinguished from not only renal or uræmic asthma, but also true bronchial asthma and the spasmodic attacks of shortness of breath which occur so frequently in advanced emphysema and chronic bronchitis. In the cardiac condition there may be little in the lungs at first, but with failure the degree of congestion may simulate the bronchitic condition, and the cardiac responsibility for the attack may be overlooked. Cardiac pain itself requires care in diagnosis, as to whether true angina pectoris is present or not. Angina should be defined as 'severe paroxysmal cardiac pain, related to effort, and having a characteristic and definite distribution'. It occurs, as a sign of myocardial exhaustion, as one of the symptoms of heart failure; and also as an association of coronary disease, pointing to coronary narrowing or occlusion, the symptoms of the last-named condition, however, being somewhat different from those of angina.

The characteristics of true angina are:—(1) The presence of an exciting stimulus, usually effort, but sometimes emotion, gastric distension, or cold; (2) a sudden paroxysmal onset, reaching its maximum almost at once; (3) severity varying from substernal tightness to a constricting crushing pain with imminent fear of death; (4) precordial, or epigastric, to begin with, radiating thence to the left axilla, arm, wrist, and inner two fingers, or to left side of neck, shoulder and jaw, or, in rarer cases, to similar situations on the right side; (5) the attitude and behaviour of the patient, who is afraid to move, waves away assistance, is ashen in colour, and breathes in a constrained way, probably with hand pressed over his heart; and (6) the sudden or rapid termination of the attack, often with passage of urine or flatus, leaving the patient exhausted, and perhaps the subject of recurrent attacks over a period of hours. Sudden death may occur in the attack.

Compare this with a coronary thrombosis: (1) The onset often when at rest, or in bed at night; (2) an agonizing pain, worse than anything ever experienced before, with much the same distribution as in angina; (3) a patient writhing in agony, restless, even walking about, anxious, sweating, ashen or even cyanosed, and dyspnoeic; (4) the pain not spasmodic, but constant and lasting even several days, and no relief except from morphia, a pulse rate over 100 and commonly irregular. Certain cases of thrombosis suffer from urgent dyspnoea, and to a much less degree from pain.

Into the further signs of these conditions I will not go now, but I will mention the other causes of apparent cardiac pain from which they have to be distinguished. These are: (1) fibrositis of the inter-costal muscles, if of the left side—sometimes a panniculitis also simulates; (2) pleurisy, which is related, of course, to respiration, and therefore may superficially be related to effort; (3) gastric pain, which may be substernal or precordial; but which does not radiate as angina does, and while angina may come on after food it usually requires exertion.

or emotion as well to excite it; (4) exhaustion of the respiratory muscles, a not uncommon cause of pain in heart failure, as the excessive respiratory strain tires the muscles; and, as the respiratory disturbances are often most painful while lying on the back, the so-called 'angina at rest' may be caused; and (5) false angina, commonest in women, and symptomatic of a lowered threshold to pain in neurasthenic individuals. These conditions must be excluded before the other serious diagnoses are made. For the relief of the pain, angina spells nitrites, and coronary thrombosis spells morphia, and morphia in large and repeated doses.

Another sign I have mentioned of chronic myocardial disease is abnormal rhythm, most commonly extrasystole or block, partial or complete. Extrasystole of itself is not a sign of cardiac disease, and it must be considered together with other indications, but heart-block is a definite sign of value as pointing to the state of the rest of the heart muscle. There is little clinical sign of disease of most of the muscle, and hence a sign of disease of part of it—the conducting tissue—is valuable because the disease process is rarely confined to that tissue. Of itself, if localized, the lesion may cause no disability; apart from the danger of Stokes-Adams' attacks, where the heart may not start again, a heart with complete block established may carry on very well, but almost always the trouble elsewhere causes a progressive failure, or, most commonly, sudden death. Various drugs have been tried in order to abolish the tendency to Stokes-Adams' attack; opinions differ, but probably barium chloride in doses of 3 grains a day, 1 gr., *t.d.s.*, or ephedrine, $\frac{1}{2}$ gr., *t.d.s.*, may be of use.

In patients past middle age, the electrocardiogram is undoubtedly a better judge of the condition of the muscle than a clinical opinion, and, therefore, in cases of doubt, if it is possible, such a record should be obtained. The same does not apply to younger patients, where a careful clinical examination will yield as good results.

In the treatment of failure due to chronic myocardial degeneration, I have been impressed with the value of glucose. In urgent cases, where absorption is likely to be deficient, it may be given intravenously as 20 c.cm. of a 20 per cent solution, following on a venesection when such is required: in most cases it is enough to give it by the mouth, either as such, or as sugar which many Indian patients will take quite well, and insulin in doses of 5 units 15 minutes or so before a dose of 2 ounces of glucose is often of help. When there is acidosis, and if there is acetone present in the urine, glucose should be given in large amounts—quite $\frac{1}{2}$ lb. (one *pao*) a day.

Where there is much œdema the best diuretic to use is one of the new mercurial derivatives, neptal or salyrgan, which acts better if given

simultaneously with one of the acid-forming salts, such as ammonium chloride, which we use here in doses of 30 gr., *t.d.s.* Digitalis in cases of myocardial failure is apt to be disappointing, and should be used with caution, especially if there is partial block; when complete block is present good results may be obtained from the direct action of the drug on the ventricular muscle, without any slowing of the heart rate.

The utility of massage must not be forgotten in restarting efficient circulation in the extremities, and in the convalescent stage it will be combined with active as well as passive movement.

Enough of the cardiovascular system. Let us now, for a short time, consider the diseases which are likely to be met with in the older patient, in the respiratory organs. The bronchi and lungs in the latter half of life are very prone to infection. A typical group of statistics gives the incidence of pneumonia per 100,000 of population, ages 15 to 45 as 100, ages 45 to 65 as 263, and 65 and over as 733. Well has it been called 'the old man's friend', removing him by a sharp and not too painful illness instead of his becoming the subject of a long-drawn-out degenerative process. Chronic bronchitis looms large in our view, with the sequels of emphysema and consequent right-heart failure. Much can, I am sure, be done, with the co-operation of the patient, to avoid the early stages of naso-pharyngo-bronchial infection which on the one hand may lead to pneumonia and on the other result in structural changes in the lungs and chronic disease: prophylactic vaccines have great utility in this connection, and should be given in such graded doses as to avoid much reaction.

The elderly patient with pulmonary trouble often presents himself to us in the guise of 'asthma', and then it is necessary, as I have already said, to exclude the possibility of a cardiac or renal cause for the spasmodic shortness of breath, which done, it will probably be found that the bronchial spasm is the result of infection, and the accompaniment of a certain degree of emphysema, and is not due to true asthma. The clearing up of the infection is then the most important point in treatment, and a vaccine, autogenous or mixed, may help. General health is of the greatest importance, removal of any infection elsewhere, avoidance of constipation, and of a heavy meal shortly before bedtime. With acute bronchitis, bed early in the attack is a golden rule with old people; a bed rest may be employed. I need not go into the variations in the drug treatment necessary, but inhalations often give much relief.

I have not touched upon the question of enlarged prostate, which belongs to the surgeon, nor will you expect me to talk to you of the symptoms and changes produced by the

onset of the menopause in women. I will only remind you that these symptoms go on for a much longer period than is often supposed, and that similar symptoms of more or less marked degree occur also in man, at a later age.

In conclusion, let me urge upon you to advise your elderly patients and friends to

keep an active mind; to take up, as their bodily activities diminish, some congenial task or occupation whereby their interest and intellect may be kept alive, and thus to avoid sinking into that death-in-life which is nothing but a burden to the individual himself and to his relations.

RAWALPINDI MEDICAL ASSOCIATION

The following resolution was unanimously passed at the Rawalpindi Medical Association meeting held on the 22nd January, 1936, and was telegraphed to the private secretary to His Excellency the Viceroy of India at New Delhi:

'The Rawalpindi Medical Association beg to offer the expression of sorrow on the death of our beloved sovereign King-Emperor George V and request you to kindly convey to Her Majesty the Queen Empress and the royal family our deep, respectful and loyal sympathy'.

STATE MEDICAL FACULTY OF BENGAL

FELLOWSHIP EXAMINATION—TITLE (F. S. M. F.)

1. It is hereby notified for information of the medical profession that the State Medical Faculty of Bengal has instituted the above higher examination equivalent to the doctorate of the universities by which the profession will be able to secure a coveted distinction.

2. The examination of the diploma of Fellowship is held either in medicine or in surgery and may be held once a year.

3. The examination shall be written, oral, practical and clinical.

4. Every candidate must either be a member of State Medical Faculty or possess a qualification or qualifications in medicine and surgery recognized by the Governing Body as equivalent thereto. Such qualification or qualifications must have been obtained at least two years before the examination.

5. Candidates in medicine will be required to specialize in one of the following groups of diseases, viz:—Diseases—

- (1) of the nervous system and mental diseases,
- (2) of the skin,
- (3) of the heart and circulatory system,
- (4) of the respiratory system,
- (5) of the digestive system including diseases of the liver, or

(6) of the urinary system, or

(7) tropical diseases.

Candidates in surgery will be required to specialize in surgery of one of the following description, viz:—
Surgery—

- (1) of the eye,
- (2) of the ear, nose and throat,
- (3) of the skull, brain and spinal cord,
- (4) obstetrical and gynaecological surgery,
- (5) of the bones and joints including orthopaedic surgery, or
- (6) of the urinary and generative system.

N.B.—For further particulars apply to the Secretary, State Medical Faculty of Bengal, Grosvenor House, Calcutta.

TRAINING OF WOMEN FOR CITIZENSHIP OVERSEA

Chairman and Treasurer.—Cyril Norwood, M.A., LL.D., President of St. John's College, Oxford.

Executive Committee.—R. E. H. Baily, C.B.E., Mrs. John Coatman, M.A., Lady Davson, O.B.E., Mrs. S. Neville-Rolfe, O.B.E., A. P. Newton, M.A., D.Litt., B.Sc., F.S.A., and M. J. Rendall, C.M.G., M.A., LL.D.

1. A non-residential course lasting ten weeks arranged by the Joint Committee of the Empire Citizenship Training Council and the Imperial Studies Committee under the aegis of the Royal Empire Society.

2. The course will start in London on 1st May, 1936, and will comprise a description of the History, Constitution and Races of the Empire, courses on Household management, and an insight into Social Services with an indication as to how these are adapted for conditions overseas.

3. An experienced whole-time tutor will be in charge.

4. Candidates should apply to the Secretary, Training of Women for Citizenship Oversea, The Royal Empire Society, 17, Carlton House Terrace, London, S.W.1, from whom information may be obtained.

5. Inclusive fee for the course, £12-12-0.

Pharmacological Aspect of Digitalis Therapy

By A. FRAENKEL, M.D.

(Abstracted from the *Lancet*, Vol. II, No. 16, 1935, p. 1101)

DIGITALIS AND STROPHANTHIN

The intravenous administration of strophanthin has made it possible to study the effect of digitalis upon the course of these processes in man with methods as exact as those used in experiments on animals. Only patients with severe dyspnoea have to be excluded from such investigations. Now recent experiments

leave no room for doubt that the main effect of digitalis in heart failure is an increase in the stroke volume and a change in the distribution of blood resulting from the increased circulation rate. Such an effect can be obtained with no other drug. The absence of appreciable effect on the healthy, as on the diseased heart when functionally compensated, and its appearance after minute doses in decompensation, may perhaps be explained in part by the intramuscular development of a specific sensitivity to digitalis in this latter group. For it is known from Weese's experiments that the intravenous injection of the glucoside is followed by the fixation of about 10 per cent of the dose by the heart:

or emotion as well to excite it; (4) exhaustion of the respiratory muscles, a not uncommon cause of pain in heart failure, as the excessive respiratory strain tires the muscles; and, as the respiratory disturbances are often most painful while lying on the back, the so-called 'angina at rest' may be caused; and (5) false angina, commonest in women, and symptomatic of a lowered threshold to pain in neurasthenic individuals. These conditions must be excluded before the other serious diagnoses are made. Pharmacological Aspect of Digitalis Therapy

By A. FRAENKEL, M.D.

(Abstracted from the *Lancet*, Vol. II, No. 16, 1935, p. 1101)

DIGITALIS AND STROPHANTHIN

THE intravenous administration of strophanthin has made it possible to study the effect of digitalis upon the course of these processes in man with methods as exact as those used in experiments on animals. Only patients with severe dyspnoea have to be excluded from such investigations. Now recent experiments

leave no room for doubt that the main effect of digitalis in heart failure is an increase in the stroke volume and a change in the distribution of blood resulting from the increased circulation rate. Such an effect can be obtained with no other drug. The absence of appreciable effect on the healthy, as on the diseased heart when functionally compensated, and its appearance after minute doses in decompensation, may perhaps be explained in part by the intramuscular development of a specific sensitivity to digitalis in this latter group. For it is known from Weese's experiments that the intravenous injection of the glucoside is followed by the fixation of about 10 per cent of the dose by the heart.

If, as has been done by Clark, we calculate the amount of strophanthin fixed per gramme of heart muscle, the astonishing fact is revealed that 1 g. adsorbs at most 0.002 mg. of the drug. If, moreover, we assume that a compensated heart has undergone an increase in weight by 50 per cent, and if we further take into account the fact that one-tenth of the lethal dose has a detectable effect upon the diseased heart exhibiting a high sensitivity to digitalis, we arrive at the conclusion that the concentration in which digitalis acts is of the same order as that found in the case of the hormones.

To the question whether or no there arises a specific increase in sensitivity to digitalis when the heart fails, no definite answer can as yet be given, owing to lack of clinical and especially experimental evidence. Weese points out that since the minute output of the 'decompensated' heart is diminished, the possibility arises of a greater proportion of the total strophanthin injected reaching the coronary system and being fixed by the heart muscle.

The fact that disagreement in the theory of strophanthin therapy is associated with unanimity as regards the practical success of treatment with the drug, shows that much still remains to be accomplished by clinical investigation. Unfortunately we still lack methods which are easily applicable in everyday practice for the estimation of stroke volume and minute output of the true that the physician finds a possible indication of these values in measurements of systolic, diastolic, and pulse pressures. In addition x-ray photography and measurement of the venous pressure (the latter rightly emphasized by Lewis) are at his disposal for assessment of the degree of heart failure and of its therapy. Here, however, I should like to invite attention to two further methods of value in this connection.

First, the daily measurement of body-weight excludes the possibility of neglecting the extrarenal loss of water—an error which easily occurs if only the urine output is determined—and indicates by direct means the day on which the removal of œdema fluid is completed, and so the time when the minute volume has in all probability reached its optimum. Exact observation of this kind enables us to avoid overdosage and at the same time, by gradation of the dose within 0.1 mg., to control accurately the rate of fluid removal, and so to delimit precisely the period allowed for complete elimination of the retained water; a realization of the therapeutic ideal of obtaining optimal effects from the smallest doses. This is illustrated in the case of a patient who showed no improvement from treatment with digitalis by mouth.

After a preliminary observation for two days, treatment with strophanthin was begun, and during the period of treatment a decrease in body-weight from 86 kg. to 71 kg. occurred. This effect was obtained by 14 injections of K-strophanthin, the initial dose being 0.3 mg. and thereafter doses of 0.4 mg. were given. A total of 5.2 mg. of strophanthin was 0.15 mg. therefore, the daily dose of strophanthin was 0.5 kg. per day. and the amount of fluid eliminated was 0.5 kg. per day. Such is a characteristic case of heart failure therapy with intravenous injection of strophanthin, the removal of œdema fluid and the course of recompensation being completely under control. At the end of treatment with strophanthin an injection of salyrgan was given, and this had no influence on the excretion of water. The giving of a provocative dose of salyrgan in such cases indicates whether or no latent œdema exists, and so supplies information of great importance in their after-treatment.

Since analogous conditions have not as yet been investigated in animals, we have already overstepped the border of experimental pharmacology. Indeed, we are immersed in the pharmacology of man immediately we ask for information from a patient as to the onset of the drug's action. And this brings us to the second means of gaining an insight into the functional state of the heart. In illness which, in the light of subsequent treatment, is shown to respond to digitalis, almost every

patient, irrespective of his position in life, feels and comments upon a favourable reaction to the first injection, provided the dose which has been chosen is not too small. The patient uses the word 'leicht'—linguistically similar and conceptually identical in both English and German—and he expresses in this way a feeling of happiness for the relief he has found. This 'subjective indicator' either appears once only, or it may be met with after subsequent injections. Its disappearance is characteristic of the completion or approach of compensation; its reappearance signifies a new failure, threatened or already present. The cause of this 'subjective indicator' has not yet been ascertained; all that seems to be certain is that it precedes the demonstrable increase in the minute volume. The presumption is that it is the expression of the first return to normal in the tension of CO₂ and O₂ in the respiratory centre, resulting rapidly and indirectly from the increased circulation rate. This self-observation of the patient receives its full importance from the fact that, unlike with morphine, therapy with strophanthin is not complicated by the phenomenon of tolerance. The necessity of increasing the dose or reducing the intervals between successive injections, which may occur in the case of intravenous strophanthin therapy, always depends upon either an anatomical or a functional deterioration in the heart as a result of progressive disease.

PRINCIPLES OF STROPHANTHIN THERAPY

The essence and limitations of therapy with intravenous injections of strophanthin can be formulated in the following way:—

(1) There is no degree and no phase of cardiac insufficiency from the beginning of the disease—often difficult to gauge—to the stage of extreme abnormality in the distribution of blood along with its accompaniments, which does not respond to the intravenous administration of strophanthin. Only the compensated heart on the one hand or the dying heart on the other not yet responds or no longer responds to this treatment. Indeed, it is possible to draw conclusions of the greatest value for diagnostic and prognostic purposes from the absence of response as well as from its presence, and in the latter case from the amount of drug and the period found necessary for functional recovery to occur.

This can be seen from the collection of a group of cases characterized especially by large hearts with myocarditis—transverse diameter from 19 to 23 cm.—and by very marked œdema. In some of these cases hypertension, in some irregularities in rhythm were present; others were free from either of these complicating factors. All were treated with series of injections of strophanthin, only after treatment with digitalis by mouth had proved unsuccessful. The doses of strophanthin were so chosen that the patients lost weight to a degree not greater than 1 kg. per day. Those patients who needed little strophanthin and displayed a marked diuresis lived long. Those on the other hand who received more strophanthin and yet eliminated their retained water more slowly died within a shorter period.

(2) In strophanthin therapy it is necessary to adhere to exact dosage, and to take careful records of the effects of each and every dose, just as in experiments with animals, and even if the treatment be continued for a long time. This demand—a matter of course in the laboratory—is, in the application of most therapeutic measures, for the most part neglected. Such a procedure, being based on scientific methods, raises strophanthin therapy to the level of controlled experiment, and furnishes at the same time a guarantee of its safety.

Although the clinic considers the oral administration of digitalis to be contra-indicated in certain cases of valvular defect and disordered rhythm, the systematic use of strophanthin by the intravenous route finds successful application in such cases too. The ætiological factor becomes of less importance; the decisive

factor is the functional impairment of the heart with its accompaniments of venous stasis and deranged distribution of blood.

I should like at this stage to invite attention to two points which can best be illustrated by reference to individual cases. In mitral stenosis, in which treatment with digitalis by mouth is often difficult and even dangerous, it is possible to obtain an ideal therapeutic effect if the doses of strophanthin are small and are given at proper intervals of time. Moreover, it is by no means exclusively cases of heart failure with auricular fibrillation or frequent and regular pulse which respond to strophanthin administration. Complete success is met with even when the pulse is infrequent and regular. In these cases the muscular effect of strophanthin is more prominent than the vagal.

(3) The prognosis of cardiac insufficiency has entirely changed since the possibility has arisen through the use of strophanthin not only of enlarging the field in which treatment with digitalis is indicated, but also of making success in the treatment of certain cases more assured. The features of this disease have been further allayed since we have had at our disposal a suitable mercurial diuretic which can be given intravenously. The heroic treatment of heart failure with calomel and digitalis by mouth, dating back to Fothergill, is now replaced by one which involves the administration of salyrgan, and so supplements the effect of strophanthin in this disease. Salyrgan acts on the tissues as well as the kidneys, and possesses the outstanding advantage that it can be given intravenously, and so in an exact dosage, which when properly chosen ensures freedom from danger. The appropriate combination of both remedies, not simultaneously or on the same day even, but one after the other on different days, makes possible the removal of oedema of the severest degree as well as that of very long standing. Drainage of the legs, so irksome to patients, is avoided, and reappearance of oedema in large part prevented. Cardiac oedema is a secondary disease which can be avoided if the failing heart is treated early enough, and if, after recompensation has become established, treatment is continued for a still longer period, the duration of which must be determined in each case by circumstances. In illustration we may quote the following case:

A patient, 60 years old, with arteriosclerosis and hypertonia, a large heart (transverse diameter 18.6 cm.) and auricular fibrillation, had shown signs of heart failure for a year. His physician treated him with digitalis, giving small doses at first and large later. No improvement was detected, but instead signs of overdose (pulsus bigeminus) supervened. After a short period of observation without medication, the loss of water was initiated by salyrgan and the failure of the heart abolished by strophanthin. It may be added that we were able to avoid the appearance of pulsus bigeminus as well as other signs of toxic action, in spite of the fact that the patient received in the course of 60 days 25 injections of strophanthin of about 0.3 mg. each, amounting to 6.3 mg. of the drug. In addition a total of 16 c.cm. of salyrgan in 12 injections was given. The elimination of water resulted in a decrease of 21 kg. in body-weight, a fact which shows that the normal weight of the patient had increased by as much as 40 per cent during the development of the failure. Notice should also be taken of the fact that the elimination of oedema fluid under the influence of the diuretic salyrgan, acting on the tissues and kidney, occurs characteristically in steps, whereas during the quantitatively controlled treatment with strophanthin this loss proceeds steadily.

From the first experiments with digitalis on the frog's heart to the more recent and complicated investigations on the action of digitalis on the heart and circulation of the mammal, the path has been long and tiresome. We must not be surprised, therefore, if the practical application of pharmacological research to the reduction of the suffering and to the prolongation of the lives of patients with heart disease takes long to

achieve. This attempt, however, to evolve a rational digitalis therapy from a knowledge of experimental pharmacology, and to describe the peculiar importance of the intravenous route in connection with the glucoside which is most suitable for this mode of administration, is not to be regarded as a revolt from the customary empirical use of preparations of digitalis by mouth. By no means Withering's therapy retains its position in the treatment of heart failure where such is of not too severe a degree or of not too long a standing.

Artificial Pneumothorax in the Treatment of Lobar Pneumonia

By F. G. BLAKE, M.D.

M. E. HOWARD, M.D.

and

W. S. HULL, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CV, 9th November, 1935, p. 1489)

IN general the procedure followed has been that used by Friedmann. Thus, thirty-four of the ninety-three patients received only one treatment, usually in the neighbourhood of from 300 to 500 c.c., forty-six received only two treatments usually given from eighteen to forty-eight hours apart, while only eleven received a third and only two a fourth. Furthermore, only nine patients were given a total of more than 1,000 c.c. of air, the maximum amount given being 1,650 c.c. in each of two cases. From these data it would seem that insufficient air was introduced to cause more than a moderate collapse or retraction of the involved lobe in the great majority of the cases. As will appear later, the method of treatment which has been evolved during the course of our study differs considerably from that generally used.

The four most frequent clinical effects reported are prompt relief of pleural pain, relief of dyspnoea, diminution, often striking, in the general toxic phenomena of the disease, and a critical fall in temperature shortly after the induction of artificial pneumothorax, sometimes permanent, though often only temporary. Clear evidence is lacking, however, that pneumothorax treatment serves to cure the disease, since in the majority of the recorded cases in which treatment was not started until the fourth day of the disease or later, approximately one-half failed to exhibit any apparent modification of the natural course and outcome of the disease, and prompt critical recovery without relapse appears to have occurred in only one of nine cases treated on the second day of the disease and in only three of fifteen treated on the third.

SELECTION OF CASES

In the selection of cases for treatment it seemed to us of importance to direct our efforts primarily to a study of the effect of artificial pneumothorax on the early stages of pneumonia. Consequently all patients with unilateral pneumonia admitted to the medical service of the New Haven Hospital not later than the third calendar day of the disease during the period covered by this report have been treated without selection, twenty-four in number. The remaining eighteen patients, in whom treatment was begun on the fourth or fifth day of the disease, were arbitrarily selected.

METHOD OF TREATMENT

The technique employed has been that commonly used. Immediately following the preliminary examination of the patient an x-ray film of the chest is taken to confirm the clinical diagnosis and to make certain that the pneumonia is unilateral. Following a preliminary dose of morphine, artificial pneumothorax treatment is started. Treatments are ordinarily given with the patient in the lateral position with the pneumonic

If, as has been done by Clark, we calculate the amount of strophanthin fixed per gramme of heart muscle, the astonishing fact is revealed that 1 g. adsorbs at most 0.002 mg. of the drug. If, moreover, we assume that a compensated heart has undergone an increase in weight by 50 per cent, and if we further take into account the fact that one-tenth of the lethal dose has a detectable effect upon the diseased heart exhibiting a high sensitivity to digitalis, we arrive at the conclusion that the concentration in which digitalis acts is of the same order as that found in the case of the hormones.

To the question whether or no there arises a specific increase in sensitivity to digitalis when the heart fails, no definite answer can as yet be given, owing to lack of clinical and especially experimental evidence. Weese points out that since the minute output of the 'decompensated' heart is diminished, the possibility arises of a greater proportion of the total strophanthin injected reaching the coronary system and being fixed by the heart muscle.

The fact that disagreement in the theory of strophanthin therapy is associated with unanimity as regards the practical success of treatment with the drug, shows that much still remains to be accomplished by clinical investigation. Unfortunately we still lack methods which are easily applicable in everyday practice for the estimation of stroke volume and minute output. It is true that the physician finds a possible indication of these values in measurements of systolic, diastolic, and pulse pressures. In addition x-ray photography and measurement of the venous pressure (the latter rightly emphasized by Lewis) are at his disposal for assessment of the degree of heart failure and of its therapy. Here, however, I should like to invite attention to two further methods of value in this connection.

First, the daily measurement of body-weight excludes the possibility of neglecting the extrarenal loss of water—an error which easily occurs if only the urine output is determined—and indicates by direct means the day on which the removal of oedema fluid is completed, and so the time when the minute volume has in all probability reached its optimum. Exact observation of this kind enables us to avoid overdosage and at the same time, by gradation of the dose within 0.1 mg., to control accurately the rate of fluid removal, and so to delimit precisely the period allowed for complete elimination of the retained water; a realization of the therapeutic ideal of obtaining optimal effects from the smallest doses. This is illustrated in the case of a patient who showed no improvement from treatment with digitalis by mouth.

After a preliminary observation for two days, treatment with strophanthin was begun, and during the period of treatment a decrease in body-weight from 86 kg. to 71 kg. occurred. This effect was obtained by 14 injections of K-strophanthin, the initial dose being 0.3 mg. and thereafter doses of 0.4 mg. were given. A total of 5.2 mg. was given in 33 days. On an average, therefore, the daily dose of strophanthin was 0.15 mg. and the amount of fluid eliminated was 0.5 kg. per day. Such is a characteristic case of heart failure therapy with intravenous injection of strophanthin, the removal of oedema fluid and the course of recompensation being completely under control. At the end of treatment with strophanthin an injection of salyrgan was given, and this had no influence on the excretion of water. The giving of a provocative dose of salyrgan in such cases indicates whether or no latent oedema exists, and so supplies information of great importance in their after-treatment.

Since analogous conditions have not as yet been investigated in animals, we have already overstepped the border of experimental pharmacology. Indeed, we are immersed in the pharmacology of man immediately we ask for information from a patient as to the onset of the drug's action. And this brings us to the second means of gaining an insight into the functional state of the heart. In illness which, in the light of subsequent treatment, is shown to respond to digitalis, almost every

patient, irrespective of his position in life, feels and comments upon a favourable reaction to the first injection, provided the dose which has been chosen is not too small. The patient uses the word 'leicht'—linguistically similar and conceptually identical in both English and German—and he expresses in this way a feeling of happiness for the relief he has found. This 'subjective indicator' either appears once only, or it may be met with after subsequent injections. Its disappearance is characteristic of the completion or approach of compensation; its reappearance signifies new failure, threatened or already present. The cause of this 'subjective indicator' has not yet been ascertained; all that seems to be certain is that it precedes the demonstrable increase in the minute-volume. The presumption is that it is the expression of the first return to normal in the tension of CO₂ and O₂ in the respiratory centre, resulting rapidly and indirectly from the increased circulation rate. This self-observation of the patient receives its full importance from the fact that, unlike with morphine, therapy with strophanthin is not complicated by the phenomenon of tolerance. The necessity of increasing the dose or reducing the intervals between successive injections, which may occur in the case of intravenous strophanthin therapy, always depends upon either an anatomical or a functional deterioration in the heart as a result of progressive disease.

PRINCIPLES OF STROPHANTHIN THERAPY

The essence and limitations of therapy with intravenous injections of strophanthin can be formulated in the following way:—

(1) There is no degree and no phase of cardiac insufficiency from the beginning of the disease—often difficult to gauge—to the stage of extreme abnormality in the distribution of blood along with its accompaniments, which does not respond to the intravenous administration of strophanthin. Only the compensated heart on the one hand or the dying heart on the other not yet responds or no longer responds to this treatment. Indeed, it is possible to draw conclusions of the greatest value for diagnostic and prognostic purposes from the absence of response as well as from its presence, and in the latter case from the amount of drug and the period found necessary for functional recovery to occur.

This can be seen from the collection of a group of cases characterized especially by large hearts with myocarditis—transverse diameter from 19 to 23 cm.—and by very marked oedema. In some of these cases hypertonia, in some irregularities in rhythm were present; others were free from either of these complicating factors. All were treated with series of injections of strophanthin, only after treatment with digitalis by mouth had proved unsuccessful. The doses of strophanthin were so chosen that the patients lost weight to a degree not greater than 1 kg. per day.

Those patients who needed little strophanthin and displayed a marked diuresis lived long. Those on the other hand who received more strophanthin and yet eliminated their retained water more slowly died within a shorter period.

(2) In strophanthin therapy it is necessary to adhere to exact dosage, and to take careful records of the effects of each and every dose, just as in experiments with animals, and even if the treatment be continued for a long time. This demand—a matter of course in the laboratory—is, in the application of most therapeutic measures, for the most part neglected. Such a procedure, being based on scientific methods, raises strophanthin therapy to the level of controlled experiment, and furnishes at the same time a guarantee of its safety.

Although the clinic considers the oral administration of digitalis to be contra-indicated in certain cases of valvular defect and disordered rhythm, the systematic use of strophanthin by the intravenous route finds successful application in such cases too. The ætiological factor becomes of less importance; the decisive

factor is the functional impairment of the heart with its accompaniments of venous stasis and deranged distribution of blood.

I should like at this stage to invite attention to two points which can best be illustrated by reference to individual cases. In mitral stenosis, in which treatment with digitalis by mouth is often difficult and even dangerous, it is possible to obtain an ideal therapeutic effect if the doses of strophanthin are small and are given at proper intervals of time. Moreover, it is by no means exclusively cases of heart failure with auricular fibrillation or frequent and regular pulse which respond to strophanthin administration. Complete success is met with even when the pulse is infrequent and regular. In these cases the muscular effect of strophanthin is more prominent than the vagal.

(3) The prognosis of cardiac insufficiency has entirely changed since the possibility has arisen through the use of strophanthin not only of enlarging the field in which treatment with digitalis is indicated, but also of making success in the treatment of certain cases more assured. The features of this disease have been further allayed since we have had at our disposal a suitable mercurial diuretic which can be given intravenously. The heroic treatment of heart failure with calomel and digitalis by mouth, dating back to Fothergill, is now replaced by one which involves the administration of salyrgan, and so supplements the effect of strophanthin in this disease. Salyrgan acts on the tissues as well as the kidneys, and possesses the outstanding advantage that it can be given intravenously, and so in an exact dosage, which when properly chosen ensures freedom from danger. The appropriate combination of both remedies, not simultaneously or on the same day even, but one after the other on different days, makes possible the removal of oedema of the severest degree as well as that of very long standing. Drainage of the legs, so irksome to patients, is avoided, and reappearance of oedema in large part prevented. Cardiac oedema is a secondary disease which can be avoided if the failing heart is treated early enough, and if, after recompensation has become established, treatment is continued for a still longer period, the duration of which must be determined in each case by circumstances. In illustration we may quote the following case:

A patient, 60 years old, with arteriosclerosis and hypertonia, a large heart (transverse diameter 18.6 cm.) and auricular fibrillation, had shown signs of heart failure for a year. His physician treated him with digitalis, giving small doses at first and large later. No improvement was detected, but instead signs of overdose (pulsus bigeminus) supervened. After a short period of observation without medication, the loss of water was initiated by salyrgan and the failure of the heart abolished by strophanthin. It may be added that we were able to avoid the appearance of pulsus bigeminus as well as other signs of toxic action, in spite of the fact that the patient received in the course of 60 days 25 injections of strophanthin of about 0.3 mg. each, amounting to 6.3 mg. of the drug. In addition a total of 16 c.cm. of salyrgan in 12 injections was given. The elimination of water resulted in a decrease of 21 kg. in body-weight, a fact which shows that the normal weight of the patient had increased by as much as 40 per cent during the development of the failure. Notice should also be taken of the fact that the elimination of oedema fluid under the influence of the diuretic salyrgan, acting on the tissues and kidney, occurs characteristically in steps, whereas during the quantitatively controlled treatment with strophanthin this loss proceeds steadily.

From the first experiments with digitalis on the frog's heart to the more recent and complicated investigations on the action of digitalis on the heart and circulation of the mammal, the path has been long and tiresome. We must not be surprised, therefore, if the practical application of pharmacological research to the reduction of the suffering and to the prolongation of the lives of patients with heart disease takes long to

achieve. This attempt, however, to evolve a rational digitalis therapy from a knowledge of experimental pharmacology, and to describe the peculiar importance of the intravenous route in connection with the glucoside which is most suitable for this mode of administration, is not to be regarded as a revolt from the customary empirical use of preparations of digitalis by mouth. By no means Withering's therapy retains its position in the treatment of heart failure where such is of not too severe a degree or of not too long a standing.

Artificial Pneumothorax in the Treatment of Lobar Pneumonia

By F. G. BLAKE, M.D.

M. E. HOWARD, M.D.

and

W. S. HULL, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CV, 9th November, 1935, p. 1489)

In general the procedure followed has been that used by Friedmann. Thus, thirty-four of the ninety-three patients received only one treatment, usually in the neighbourhood of from 300 to 500 c.c., forty-six received only two treatments usually given from eighteen to forty-eight hours apart, while only eleven received a third and only two a fourth. Furthermore, only nine patients were given a total of more than 1,000 c.c. of air, the maximum amount given being 1,650 c.c. in each of two cases. From these data it would seem that insufficient air was introduced to cause more than a moderate collapse or retraction of the involved lobe in the great majority of the cases. As will appear later, the method of treatment which has been evolved during the course of our study differs considerably from that generally used.

The four most frequent clinical effects reported are prompt relief of pleural pain, relief of dyspnoea, diminution, often striking, in the general toxic phenomena of the disease, and a critical fall in temperature shortly after the induction of artificial pneumothorax, sometimes permanent, though often only temporary. Clear evidence is lacking, however, that pneumothorax treatment serves to cure the disease, since in the majority of the recorded cases in which treatment was not started until the fourth day of the disease or later, approximately one-half failed to exhibit any apparent modification of the natural course and outcome of the disease, and prompt critical recovery without relapse appears to have occurred in only one of nine cases treated on the second day of the disease and in only three of fifteen treated on the third.

SELECTION OF CASES

In the selection of cases for treatment it seemed to us of importance to direct our efforts primarily to a study of the effect of artificial pneumothorax on the early stages of pneumonia. Consequently all patients with unilateral pneumonia admitted to the medical service of the New Haven Hospital not later than the third calendar day of the disease during the period covered by this report have been treated without selection, twenty-four in number. The remaining eighteen patients, in whom treatment was begun on the fourth or fifth day of the disease, were arbitrarily selected.

METHOD OF TREATMENT

The technique employed has been that commonly used. Immediately following the preliminary examination of the patient an x-ray film of the chest is taken to confirm the clinical diagnosis and to make certain that the pneumonia is unilateral. Following a preliminary dose of morphine, artificial pneumothorax treatment is started. Treatments are ordinarily given with the patient in the lateral position with the pneumonic

side up, since the intrapleural pressure established with the patient in this position does not become lower in any other position that the patient may subsequently take. Air is allowed to flow in under the negative pressure developed during inspiration until the intrapleural pressure has nearly reached the atmospheric level, when a slightly positive pressure is used. Pressure readings are taken after every 50 to 100 cubic centimetres of air have been introduced, the treatment being continued until the desired intrapleural pressure is attained. If (for any reason) it is found necessary to have the patient in the prone or sitting position during the treatment, the mean pressure should ordinarily be raised to about 4 cm. higher than the desired level in the lateral position since the pressure will fall approximately 4 cm. whenever the patient changes from the prone to the lateral position with the pneumothorax side up. If, during the treatment, the patient complains of a dragging or pulling pain, adhesions may be suspected and the treatment may be interrupted. Following the first, second or third treatment, as seems indicated, another x-ray film is taken to determine the degree of collapse of the lung and the presence or absence of pleural adhesions.

The procedure followed with respect to the frequency, rate and volume of pneumothorax treatments has been evolutionary and empirical and will be illustrated by early, intermediate and recent cases in the series.

In the beginning it was hoped that two initial treatments of approximately 300 to 500 c.c. each, given six hours apart and followed, if necessary, by a third treatment eighteen hours later, might be sufficient to accomplish the desired result. This procedure was found to establish a mantle pneumothorax without selective collapse of the involved lobe and to raise the mean intrapleural pressure to -3 to -0.5 cm. It appeared to be satisfactory in the first two cases treated. By the time nine cases had been treated, however, it had become apparent that this procedure was inadequate, since, following temporary clinical improvement, relapse was found to occur as the intrapleural pressure fell, provided antibodies had not appeared in the blood, as was subsequently found to have happened in the first two cases.

In view of these results the procedure was changed. From three to five initial treatments were given at intervals of approximately four hours in order to establish a mean intrapleural pressure in the neighbourhood of $+1$ cm. to $+2$ cm. and to induce a complete collapse of the whole lung on the involved side, provided adhesions did not interfere. The first three treatments were ordinarily of 500 to 800 c.c. each. Subsequent treatments were given at irregular intervals in an effort to maintain a positive intrapleural pressure and complete collapse of the lung until permanent recovery seemed assured or further treatment inadvisable. Gradually a further modification was tried, in which the initial treatment was increased in amount and the early refills were given at somewhat less frequent intervals. At the same time, with the purpose of avoiding temporary increase in dyspnoea, the rate of introduction of air was cut down from an average rate of approximately 30 to 40 c.c. per minute, which had been previously used, to an average rate of 10 to 15 c.c. per minute. At this slow rate, large amounts of air can apparently be administered without difficulty.

The volume of air required to raise the mean intrapleural pressure to $+1$ cm. to $+2$ cm. has been found to vary greatly from case to case and cannot at present be correlated with any measurable factors, nor can it be predicted. Ordinarily it will range from 1,800 to 2,400 c.c. The time required for the large initial treatment consequently will vary. If 1,800 c.c. is given and it is administered at an average rate of 12 c.c. per minute, the treatment will take two and one-half hours to complete. The rate of fall in intrapleural pressure following the first treatment has been found to be very variable and unpredictable, ranging from 0 to 1.33 cm. ap hour in the cases studied. The rate of fall following

refills is likewise variable, though commonly less rapid than after the first treatment. Consequently the frequency and volume of refills required to maintain a positive intrapleural pressure and complete collapse of the lung are at present empirical. In our experience not more than four to eight hours should be allowed to elapse between the first and second and the second and third treatments, decision as to time in the individual case depending in part on the pressure level attained at the end of the first treatment, in part on the volume of air previously introduced and in part on the clinical response. The use of subsequent refills depends on the course of events in the individual case. In general, an effort is made to keep the intrapleural pressure positive until recovery seems assured.

EFFECT OF PNEUMOTHORAX TREATMENT

Review of the forty-two cases treated suggests that the most important factor influencing the results, apart from the method of treatment used, is the duration of the disease at the time treatment is instituted. Consequently our cases have been divided into four groups, according to duration. Group A comprises four cases in which treatment was begun within twenty-four hours after onset in the preconsolidative stage; group B, nine cases in which treatment was started between twenty-four and forty-eight hours after onset in the early consolidative stage; group C, fifteen cases in which treatment was initiated between forty-eight and seventy-two hours after onset with hepatization more or less advanced, and group D, fourteen advanced cases of more than seventy-two hours' duration when treatment was begun. Another important factor apparently influencing the results in groups B and C at least is the absence or presence of pre-existing fibrous pleural adhesions; consequently these two groups have been subdivided accordingly. Since the effect of artificial pneumothorax in relieving some of the distressing symptoms of lobar pneumonia, such as pleural pain, restlessness, dyspnoea and toxæmia, has been well described by others and our experience is in harmony with theirs, this subject will not be elaborated here and attention will be directed towards the effect of pneumothorax therapy on the course, duration and outcome of the disease.

GROUP A: Treatment begun within twenty-four hours after onset.—It will be seen that all four patients were treated with large initial amounts of air, the mean intrapleural pressure being raised to the positive level. Complete collapse of the whole left lung occurred in all but one case in whom adhesions between the parietal and the visceral pleura over the uninvolved left upper lobe prevented collapse of this lobe. All four patients recovered promptly without further extension of the pneumonia and without complications, except for a transient acute psychosis in W. L., a patient suffering from severe chronic alcoholism.

GROUP B: Treatment begun between twenty-four and forty-eight hours after onset.—In the first six cases without adhesions all but one, who was treated early in the series, received initial treatments adequate to raise the mean intrapleural pressure to atmospheric level or above and to collapse the whole lung on the involved side. All showed prompt clinical improvement with relief of distressing symptoms. Recovery was rapid in one and apparently accelerated in all but R. F., who nevertheless was much improved symptomatically. None showed further spread of the pneumonia. In two cases sterile pleural effusions developed that were sufficiently large to warrant withdrawal by aspiration. No notable effect on the symptoms or course of the disease resulted in the three cases in which pleural adhesions were present, presumably because the adhesions interfered with adequate collapse of the involved lung. Three patients in group B showed a transient bacteræmia following the institution of pneumothorax therapy, apparently without ill effect.

GROUP C: Treatment begun between forty-eight and seventy-two hours after onset.—Of the six patients

without pleural adhesions four recovered promptly by crisis, two showed temporary improvement but relapsed, with a spread to the opposite side. Three, however, showed antibodies in the blood on the fifth, third and sixth days, respectively, so that early recovery may have been the natural crisis rather than related to the pneumothorax treatment. Among the nine patients with fibrous pleural adhesions no beneficial therapeutic effect was observed, with one possible exception.

GROUP D: Treatment later than seventy-two hours after onset.—Artificial pneumothorax exerted no apparent effect on the duration or outcome of the disease in this group of advanced cases. In fact, even temporary symptomatic relief was observed in only one patient. In none of the six cases in which bacteremia was present did the treatment terminate the blood stream infection.

COMMENT

The observations on the use of artificial pneumothorax in the treatment of forty-two cases of lobar pneumonia that have been presented appear to indicate that the procedure is of definite therapeutic value but only under certain limited conditions; namely, (1) when the volume of air introduced into the pleural cavity is sufficient to raise the mean intrapleural pressure promptly to a level of +1 to +2 centimetres with the patient in the lateral position, pneumonic side up, resulting in complete retraction of the affected lung; (2) when the frequency of refills is sufficient to maintain the mean pressure at this level and the lung is retracted until the danger of relapse is past; (3) when treatment is instituted early in the disease; i.e., certainly within less than seventy-two hours after onset, probably within less than forty-eight hours in most cases; (4) when the pleura is free from adhesions that interfere with retraction of the involved lung. The signal importance of the time factor is clearly shown in figure 10, which summarizes the results in the forty-two cases treated.

Experimental observations bearing on the mechanism by which artificial pneumothorax exerts its apparent effects have been presented elsewhere and will not be discussed in detail here. In brief, they show (1) that respiratory motion of the involved lung can be abolished by artificial pneumothorax, provided the amount of air introduced is sufficient to cause maximum retraction of the lung on the treated side, (2) that antibody production is not demonstrably accelerated by pneumothorax therapy, and (3) that there is little evidence to support the view that relief of a hypothetical bronchial occlusion takes place following pneumothorax treatment. Consequently the theory that the effects of artificial pneumothorax depend on immobilization of the infected lung would appear to be the most acceptable one at present.

CONCLUSIONS

1. Artificial pneumothorax, when administered so as to induce and maintain complete collapse of the lung on the involved side, would appear to be a useful therapeutic procedure in the treatment of lobar pneumonia but only when used early in the disease, preferably within twenty-four hours after onset.
2. There is no evidence to support the view that it is of curative value later than seventy-two hours after onset.
3. Further trial of artificial pneumothorax in lobar pneumonia is desirable and should be carried out before any statistical analysis of results obtained is warranted.

Hæmorrhage and Anæmia in the Newborn

By REGINALD LIGHTWOOD, M.D., M.R.C.P., D.P.H.
(From the *Medical Press and Circular Supplement*,
23rd October, 1935, Symposium No. 4, p. xi)

In the neonatal period hæmorrhage and anæmia are closely linked. The bleeding and coagulation time,

and the number of platelets conform to the average standards which are given as the 'normals' for all ages, and quantitative analyses of the substance concerned in clotting indicate that during the first four days every factor favours increased coagulability. Nevertheless, in practice somewhat wide variations are not uncommon, and a tendency to bleed excessively must be recognized as an occasional feature of the first two weeks of life. Moreover, a little bleeding may be a serious matter when the infant's blood volume is small and when the bone marrow is already working at high pressure to supply physiological requirements. Further, when hæmorrhage causes anæmia, a vicious circle may arise, for anæmia in turn may interfere with the mechanism responsible for the arrest of bleeding.

SPONTANEOUS HÆMORRHAGE

Soon after birth hæmorrhage from the umbilicus may be seen. It is due to slipping of the ligature, which will require to be re-tied; or a ligature, too thin, may cut through the delicate tissues of the cord. It is advisable, therefore, to use a stout ligature and to apply it at such distance from the umbilicus as to make re-ligature possible. From the second day until after separation of the cord, secondary hæmorrhage due to infection may occur. Its treatment is (1) preventive and (2) immediate. The former consists in thorough asepsis and the proper care of infection if it occurs. The latter lies in the application of pressure. This may be effectively carried out by means of a long needle passed transversely under the umbilicus. Pressure can then be exerted by a figure-of-eight of coarse silk wound round the needle. Small bleeding granulomata may be touched with a stick of silver nitrate. To confer a measure of passive resistance to infection, an intramuscular injection of 5 to 10 cubic centimetres of the mother's whole blood may be given.

Melæna neonatorum, the hæmorrhagic disease of the newborn, is a well-defined clinical entity, probably due to some qualitative alteration in the blood. The nature of this alteration is not known. Shallow duodenal ulcers have been found in a few fatal cases, but their causal relationship has not been satisfactorily established, for they have also been found in cases without hæmorrhage. The number of platelets is within normal limits; in some of the patients the coagulation time is prolonged. In the majority of cases the bleeding comes from the gastro-intestinal tract, consequently melæna is the chief symptom, though hæmatemesis alone or in association with melæna is frequently seen. More rarely the hæmorrhage takes its origin from some other mucous surface or from the umbilicus; if from the latter, signs of infection should be sought. The onset of melæna neonatorum is from the first to the third day, though occasionally it may be delayed, and cases beginning as late as the tenth day have been recorded. Quite healthy-looking infants may be affected.

In so far as untreated cases may prove rapidly fatal, this melæna must be regarded as a medical emergency. On the other hand, mild, untreated cases often recover spontaneously, though liable to anæmia at a later date. Few diseases are more easily treated. As soon as the condition is recognized, 10 to 15 cubic centimetres of human whole blood (the serum does equally well, but the added trouble of removing the cells is not necessary) should be injected intramuscularly. Sometimes more than one injection is required; when this is the case, the second injection should follow within two to four hours. A total of 30 cubic centimetres in all may be required. There is direct evidence that the bleeding may abruptly cease about ten minutes after a successful injection. The blood need not be grouped; citration may be carried out, but only as a convenience to prevent clotting in the syringe. (For citration, dissolve a two-grain tablet of sodium citrate in 3 cubic centimetres of water and add 1 cubic centimetre to 10 cubic centimetres of blood). The injection is made into the muscles on the outer side of the thigh, avoiding the napkin area. Afterwards the infant

must be kept warm and quiet in its cot for twenty-four hours. Three hours after effective treatment, feeding is begun again with due caution. Occasionally a severe hæmorrhage, or delay in giving the treatment, results in a state of anæmia dangerous enough to demand blood transfusion, which is indicated if the blood count falls below three million cells; but the intramuscular injection must not be delayed during preparation of the transfusion. In convalescence, iron deficiency may become unmasked, and to prevent this, reduced iron, one-half grain, powdered, mixed with sugar and placed on the infant's tongue, three times a day, is valuable.

All other causes of spontaneous hæmorrhage are rarer than the foregoing. Purpura may be seen, either the thrombocytopenic variety or secondary purpura due to septicæmia. Hæmophilia may show itself when an hereditary affected infant is circumcised. Leukæmia is a very rare cause of bleeding in the newborn.

Hæmorrhage associated with jaundice.—An increased tendency to bleed is a notable feature of jaundice whatever its cause, so that it may arise in any of the icteric conditions encountered in the neonatal period. In *icterus gravis neonatorum* spontaneous hæmorrhage is one of the recognized causes of death. It may be gastro-intestinal, umbilical, subcutaneous or intracranial. Similarly in *congenital obliteration of the bile ducts*, *sepsis neonatorum* and *congenital syphilis* with jaundice, bleeding may occur and, indeed, prove fatal. There are also two kinds of severe neonatal infection distinguished by the eponyms of *Winckel's* disease and *Buhl's* disease; both used to have rare epidemic incidence until the introduction of aseptic technique in obstetric practice, and now they have virtually disappeared. *Winckel's* disease, also called epidemic hæmoglobinuria, was a septicæmic condition due to umbilical infection in which grave toxæmia caused jaundice, rapid blood destruction, hæmoglobinuria and hæmorrhages. The combination of jaundice and cyanosis induced different observers to mention the occurrence in their cases of a somewhat characteristic bronze or slaty-grey colour. *Buhl's* disease was a fatal gastro-enteritis featured by jaundice, hæmorrhage, œdema, intense fatty changes in the viscera and enlargement of the liver. In these syndromes an hepatitis was the cause of the jaundice and hæmorrhage was a manifestation of toxæmia.

Suprarenal hæmorrhage may occur in the newly born, and the condition, when bilateral, is incompatible with life. Characteristic are the presence of high temperature and rapid respiration, with normal lungs, so that differential diagnosis includes pneumonia. A mass may be felt at the adrenal site; convulsions, petechiæ, purpura, erythematous rashes and jaundice may later appear.

ANÆMIA IN THE NEONATAL PERIOD

We have much to learn in regard to the ætiology and pathology of the clinical varieties of anæmia, some common and some very rare, which occur in the neonatal period. Their classification is therefore difficult. Provisionally, the following scheme may be followed:

Category	Examples
I. Hæmolytic anæmias.	Icterus gravis neonatorum; hæmolytic anæmia of the newly born; anæmia of neonatal syphilis, and family acholuric jaundice.
II. Anhæmopoietic anæmias.	Hypoplastic anæmias due to bone marrow insufficiency, iron-deficiency, infections.
III. Mixed types, both hæmolytic and anhæmopoietic.	Anæmia of prematurity; erythronoclastic anæmia resulting from infection in the newly born.
IV. Leukæmias	

Hæmolytic anæmias.—It is well known that during the first seven to ten days of life the majority of

infants show evidence of a physiological hæmolysis (physiological icterus) which is explained by the theory that the full time unborn infant, depending on placental respiration, requires a higher proportion of red cells and of hæmoglobin than will be necessary after pulmonary respiration becomes established. The mechanism by which the excess of circulating erythrocytes is broken down has not been explained.

An hyperchronic anæmia developing rapidly in the first few days after birth is the rule in the already mentioned *icterus gravis neonatorum*. Its hæmolytic character is shown by a positive indirect van den Bergh reaction (the direct reaction may also be positive at the height of the jaundice), a high colour index, brisk regeneration of blood and, in fatal cases, hæmosiderosis of the viscera. Some would see in this condition an exaggeration of the physiological hæmolysis of healthy neonates, while others have preferred to postulate a primary disorder of erythropoiesis. Pathologically many of the cases show widespread extramedullary hæmatopoiesis in the liver, spleen and other tissues. Nucleated red cells are numerous in the blood (erythroblastæmia). The death rate from anæmia and jaundice, and sometimes from hæmorrhage or infection, is high, and destructive changes in the nuclei of the medulla and basal ganglia (kernicterus) also contribute to the mortality. Treatment may be directed (1) towards an attempt to check further blood destruction. This is essayed by intramuscular injections of human blood serum; 5 to 15 c.c. given as early as possible and repeated daily until improvement begins; (2) towards prevention of an issue fatal through anæmia by the use of whole blood transfusions.

Similar in type is the condition of *hæmolytic anæmia of the newly born*, which may be related to icterus gravis, but differs from it in the absence or mildness of jaundice and the lesser number of nucleated red cells in the blood. It is unusual to discover the cause of this kind of neonatal anæmia, but sometimes an infection, e.g., severe neonatal syphilis, streptococcal or staphylococcal fever, is present; and the anæmia and hæmoglobinuria of *Winckel's* disease may be recalled.

Anhæmopoietic anæmias.—Defective blood formation in the neonate is seldom due to any known specific deficiency. For example unless the mother herself is the subject of severe hypoferrism, iron lack is rare at this age. On the other hand, we are ignorant of nearly all other possible causes. Scantiness of marrow tissue, the anatomical result of limited medullary bone space, which overcrowds and restricts the output of blood cells, suggests an attractive hypothesis. Certain cases may result from infection through depressed marrow function (inhibitory anhæmopoietic anæmia). For all our ignorance of their causation, clinically these cases are striking. A sudden pallor, without trace of jaundice or hæmolysis, comes a few days after birth ('congenital anæmia'). The van den Bergh reaction is negative and signs of blood regeneration are absent. Iron is without effect, and liver extract, though not of proven value, is worth trial. In all cases except the mildest whole blood transfusion is the only effective treatment. If after a time spontaneous regeneration begins the prognosis is good, but failing this the aspect of idiopathic aplastic anæmia is assumed and the infant dies.

Mixed types of anæmia.—It must be recognized that the causes of any one case of anæmia may be multiple; for example, during a pyogenic infection, hæmoglobin may be lost through secondary hæmorrhage, and subsequent regenerative activity of the bone marrow may be prevented by toxæmia. The *anæmia of premature infants* has a background equally complex. In them the ordinary physiological hæmolysis is apt to be excessive; then, from immaturity of the bone marrow, from defective iron storage and perhaps from other factors, subsequent erythropoiesis is delayed. For these reasons moderate hæmolytic anæmia is common in the premature's first few weeks, recovery from it is slow, and later, from about the third month, the effects of iron deficiency are increasingly evident. As a rule

the early increased hæmolytic must be left to run its course, but if, soon after birth, severe anæmia is present, blood transfusion will be of value. The period of hæmolytic and icterus being past, half-grain doses of reduced iron mixed with sugar may be given three times a day. It has been shown that some premature infants have a 'negative iron balance' during their first few months, so that these prophylactic doses of iron, incapable of preventing moderate anæmia from arising, will ensure that when the infant's ability to use iron increases there will be no shortage.

In certain (hæmolytic) cases, related on the one hand to hæmolytic anæmia of the newly born and to hypoplastic anæmia on the other, following an initial destruction of blood, regeneration temporarily or permanently fails; to these the comprehensive term *erythronoclastic anæmia* is applied. In the group with temporary failure, early blood transfusions are of the greatest value. They may keep the infant alive (substitution therapy) until the bone marrow becomes efficient some three or four weeks after birth, this state of efficiency being heralded by a spontaneous reticulocytosis.

Leukæmia.—Instances are on record of infants showing leukæmia at or soon after birth. In no case, though, has the mother suffered from the disease, nor has a leukæmic mother been delivered of a leukæmic infant, evidence against any possible infective origin for leukæmia. Leukæmia in the newborn does not differ materially from the same disease occurring at a later period of childhood except that the myelogenous types, so rare in children past the age of infancy, are encountered relatively more often. Difficulties have arisen in distinguishing severe hæmolytic anæmias with erythroblastæmia (icterus gravis, etc.) from neonatal leukæmias but the signs of hæmolytic in the erythroblastic syndrome (icterus, etc.), together with the cytology of the blood films, should enable leukæmia, which is much the rarer, to be easily excluded.

Recent Advances in Dietetics

By S. J. COWELL, M.A., M.B., F.R.C.P.

(From the *Practitioner*, Vol. CXXXV, October 1935, p. 384)

THE past year or two has witnessed an exceptional degree of interest on the part of the general public in problems connected with 'food values'. Only too often, however, this legitimate interest has had to be satisfied with half-truths or guesses at the truth. The relation of diet to human health and development is still only beginning to be understood. Modern principles of nutrition have been applied for so short a time to problems of human dietaries that it will not be possible for many years to judge what may and what may not be achieved by 'correct' feeding throughout the whole span of men's lives. As far as the medical profession is concerned there are two main aspects of dietetics which merit separate consideration. There is first the use of diet for the treatment of established disease and, secondly, the use of diet for promoting good physical development and lessening the predisposition to various diseases.

TREATMENT BY DIET

As regards the use of diet therapeutically, many of the most valuable recent advances have been in the direction of supplying dietetic factors the absence of which from the habitual diet has led to deficiency states or diseases. Such deficiency diseases, though often caused primarily by dietetic faults, are sometimes treated more satisfactorily by massive doses of the missing food elements than by natural foods containing those elements. Treatment by the former method can scarcely be distinguished from treatment on orthodox pharmacological lines, although the prevention of such diseased conditions can usually be assured by adjustment of the diet alone. A good illustration of this principle is to be found in the recent work which has

been done on nutritional anæmia, particularly by Professor L. S. P. Davidson and his colleagues in Aberdeen. Anæmia, often severe, was found by them to be widespread among the women of that city, and the evidence which they laboriously collected pointed to a deficient iron intake in the daily food as one of the chief determining causes. Treatment of the condition by a good diet containing natural foods comparatively rich in iron was slow and uncertain, whereas treatment by massive doses of medicinal iron was usually effective in quite a short time. Again, deficiency diseases are now recognized in people whose diets have not been lacking in any known food factor, the deficiency having arisen either from an acquired inability to absorb some specific food factor or from some breakdown on the part of certain tissues of the body which interferes with the normal metabolism of a specific food factor. Thus among the victims of chronic intestinal diseases 'secondary pellagra' has been recognized not infrequently and its origin is probably to be sought in mal-absorption of the pellagra-preventing substance or substances. Pernicious anæmia is an example of a secondary deficiency disease in which the fault lies not in an actual food deficiency, but rather in a defective mechanism in the stomach for elaborating from certain food elements the necessary specific substance which stimulates the formation of red cells. Such secondary deficiency diseases, though not always readily amenable to simple dietary adjustment, may be readily amenable to comparatively large doses of the appropriate factors.

This tendency to employ pharmacological substances in place of natural foods is met with in the treatment of chronic urinary infections. The high fat: low carbohydrate diet which has been used with considerable success in such conditions has already a serious rival. The therapeutic effect of this diet probably depends on the production and excretion in sufficient concentration in the urine of B-oxybutyric acid, and it is well known that for the attainment of this end the diet must be most rigorously controlled, usually to the patient's great discomfort. It is now claimed that equally good results may be obtained by keeping the patient on his usual diet and giving him by mouth mandelic acid, which apparently has the same sort of effect as naturally produced B-oxybutyric acid.

DIET AND PREVENTIVE MEDICINE

Although many of the modern discoveries of nutritional science have been divorced from their natural application by way of dietary control in so far as the treatment of disease is concerned, preventive medicine should still rely mainly on the selection of a suitable dietary of natural foods to foster that state of good nutrition which favours good physical development and raises the resistance of tissues to disease. This the general public is beginning to realize. There would appear to be no doubt whatever that a great deal of preventable illness is caused directly and indirectly by imperfect diet in countries such as ours where definite deficiency diseases are, with one or two exceptions, uncommon. The difficulty at present is to define with any certainty the requisite qualities of a good diet for human beings. To collect direct evidence on such a point is obviously an undertaking of enormous magnitude which would require an elaborate organization. To judge from the newspaper controversy which raged last year on the subject, the nutrition of human beings would seem to depend on supplying them with an exact number of calories and a precise amount of first-class protein. This was, of course, due to general ignorance; every medical man knows how variable is the amount of food consumed by different individuals in comparable states of nutrition. Probably the most practical suggestion which can be given to the ordinary individual in the present state of knowledge will turn out to be the advice to include regularly in his diet liberal quantities of the so-called protective foods, dairy produce, fresh vegetables and fruit, and to leave the rest of the diet to the individual taste.

SPECIAL CASES

In the case of certain classes of individuals, however, it is becoming generally recognized that more precise care in the choice of diet will have to be exercised if adequate nutrition is to be fully attained. Children, especially during their first years of growth, and women during pregnancy, require larger proportions of protective foods to ensure that their tissues do not suffer under the strain of rapid development to which they are subject. Certain food elements are already known which are particularly likely to be lacking in the ordinary diets of individuals belonging to these classes, their deficiency not uncommonly resulting in recognizable symptoms of disease. Among these may be included the mineral elements calcium, iron and iodine and certain of the vitamins. So much has been written about the calcium requirements of children that it is not necessary to stress it in any detail. A generous supply of calcium and phosphorus, together with a liberal supply of vitamin D, is essential for the perfect development of the bones and teeth of the child. Since milk is one of the richest sources of calcium among common foods, its provision for children on a liberal scale would seem to be justified for this reason alone, and the recent agitation for making it more readily available in poor households is all to the good. It is, however, not perhaps so generally realized that the pregnant woman, especially during the last few months of her pregnancy, requires large quantities of calcium in her diet to supply her rapidly developing foetus with all it needs without sacrificing her own valuable stores. A severe degree of calcium deficiency, particularly if combined with a deficiency of vitamin D, leads, as is now well known, to osteomalacia. But minor degrees of deficiency of these elements are almost certainly related to some of the common disorders associated with pregnancy. The spread of dental caries and the painful muscular cramps which are common features of pregnancy would appear to be due to this cause and to be preventable to a large extent by appropriate measures to make good the deficiencies. Evidence is now being accumulated to show that some of the toxæmias of pregnancy may be prevented by similar means, that is by increasing the supply of calcium and vitamin D.

The question of the iron requirements during infancy and pregnancy has recently been receiving a good deal of attention. Dr. Helen Mackay has worked out with great care the frequency of anæmia among infants in the East End of London and has shown that it is of nutritional origin associated with diminished resistance to infections and that it can readily be prevented or

cured by adding to the milk diet some simple preparation of iron. Of equal importance to this nutritional anæmia of infancy would seem to be the anæmia which is frequently associated with pregnancy. The common form of anæmia during pregnancy in this country, though almost certainly of nutritional origin and associated with a deficiency of iron in the habitual diet, is most satisfactorily treated by liberal doses of medicinal iron. The recognition of this anæmia and its correction by suitable treatment are rapidly becoming more widespread in this country, and it may be possible in the next few years to determine the extent to which some of the difficulties and dangers of labour and the puerperium are due to its presence.

A word may be said on the question of iodine deficiency. An adequate supply of iodine is still to be regarded as the key to goitre prevention, but there seems little doubt that successful prophylaxis depends largely on ensuring a sufficient supply of iodine to the developing foetus, which means giving the pregnant mother iodine in some form or other. The simplest method of doing this in our country is that sea-fish should be eaten once or twice a week during pregnancy.

These few examples may serve as indications of the special food requirements of pregnant women and children. It would be idle to pretend that the knowledge exists at present to enable ideal diets to be devised which would ensure perfect physical development of the human child and promote perfect health of the mother during her pregnancy, labour and lactation. Nevertheless, it is becoming more and more apparent that wise feeding plays a large part not only in determining the health of women throughout the period of their reproduction and in regulating the development of the growing child, but it is also capable of affecting the health of the offspring in later life. It is known that the body adapts itself in a remarkable way to changes of environment, including drastic changes in dietaries. Yet there is no doubt that dietary deficiencies in early life can lead to imperfections in the growth of the tissues which cannot be repaired in later life by the most perfect diet. Direct evidence on such a point as this is not easy to obtain when dealing with human material, but the truth of the general principle is suggested most strongly by a mass of experimental data obtained from animals. In the nature of things advances in knowledge of the full prophylactic effects on human beings of a good diet are bound to be slow. The general awakening of interest in the subject both within and outside the medical profession should foster the collection of further facts dealing directly with human material without which permanent progress in dietetics must be uncertain.

Reviews

THE MEDICAL GUIDE FOR INDIA AND INDEX OF TREATMENT.—By E. J. O'Meara, O.B.E., F.R.C.S. (Eng.), D.P.H. (Cantab.), Lieut.-Colonel (retd.). Fourth Edition. 1935. Published by Butterworth and Company (India), Limited, Calcutta. Pp. xv plus 1234. Illustrated. Price, Rs. 15. Postage, extra

A BOOK of this nature is a very difficult one to produce as it is impossible for one man to be sufficiently in touch with advances in every branch of medicine and surgery to produce an up-to-date account of everything, that is free from errors. This has to some extent been overcome by the author (or perhaps more correctly the editor) having obtained the assistance of many well-known authorities to contribute sections for which they are specially qualified; thus leprosy, malaria and cholera are well and briefly dealt with by Sir Leonard Rogers; indigenous drugs by

Colonel Chopra; obstetrics in the tropics by Lieut.-Colonel Green-Armytage; and acute abdominal conditions by Lord Moynihan to mention only a few of the special contributions.

Unfortunately, the same cannot be said of many of the notes not contributed by special writers, and in a book specially prepared for use in India one is surprised to find that certain sections of great importance in this country have been very inadequately dealt with. For instance under the heading 'Worms, intestinal' one finds a single prescription for roundworms, an out-of-date and unnecessarily complicated treatment for tapeworm, several treatments for threadworms and two prescriptions, one for roundworms and one for tapeworms in children. One has to search elsewhere for treatment of hookworm infection, and here again one finds that the subject is not properly up to date, for instance carbon tetrachloride is recommended on

account of its cheapness but no caution is given regarding its toxicity if used on unsuitable cases, and tetrachlorethylene is not mentioned. In still another place under 'Ankylostomiasis' a combination of one drachm of carbon tetrachloride and 15 minims of oil of chenopodium divided into three doses is recommended but the intervals between the doses are not given.

We now turn to another typically Indian disease, kala-azar, and find it is described in three-quarters of a page. The barest details of treatment with neostibosan are given. The various stibamine preparations are mentioned but no dose is given for them, and the greater part of the section is devoted to the use of sodium and potassium antimony tartrates which are much more fully dealt with than the newer and better drugs.

The section on classification of anæmia also lacks evidence of recent revision. Under 'B. Secondary (1) from arterial hæmorrhage' one finds wounds, hæmoptysis, hæmatemesis, uterine, intestinal, and hæmorrhoids, and (3) parasitic includes *A. duodenale*, *Bilharzia hæmatobia*, *Bothriocephalus latus* and *Filaria*. Presumably *Necator americanus* is not considered worth mentioning. In this classification pregnancy anæmia is not given but this is to some extent rectified by an account of this condition under both obstetrics and gynaecology.

Yellow fever is rightly not fully discussed but that 'there is always danger of it being introduced into India from the Far East' is a distinctly misleading statement, and it would have been better to omit all mention of the disease than to include such misinformation.

There is undoubtedly a great deal of valuable information in this book and its compilation represents a great amount of hard work but it is regrettable that so many errors have been allowed to remain for if it is used as their universal guide by the not very highly trained practitioners of which we have so many in India they will often find themselves disappointed or misled when referring to its pages for help, and so the book will largely defeat the commendable object with which it has been published.

It is difficult enough to make a book of this nature of reasonable size, in spite of most careful condensation, so it is hard to understand why four pages at the end have been devoted to the calendars for the years 1935-1938.

A book of this kind is almost a necessity for the isolated and not particularly well-qualified doctor who on account of lack of means cannot afford to buy journals and expensive books on special subjects, so it is hoped that in the next edition more care will be taken in its revision for the foundation is there of a valuable contribution to medical literature in India to fulfil a definite want owing to our special circumstances, but at present the superstructure is badly constructed.

P. A. M.

CLINICAL PARASITOLOGY AND TROPICAL MEDICINE.—By Dámaso de Rivas, B.Sc., Biol. M.S., M.D., Ph.D. In collaboration with Carlos T. de Rivas, B.A., M.D. 1935. Henry Kimpton, London. Pp. 367. Illustrated with 144 engravings and a coloured plate. Price, 22s. 6d.

THERE are now a number of useful books on tropical medicine available for the student and the practitioner, but, as on the whole this particular shelf in our library is not overcrowded, this new recruit was greeted with a certain amount of pleasure; it is feared, however, that the pleasure ended here.

On opening the book, the reviewer, with a natural though myopic instinct, turned to the subject of kala-azar; here he read, 'The mode of transmission of the parasite is not well understood, but it is believed that it is transmitted by contact, through abrasions or wounds in the skin. There is also a possibility that the parasite is transmitted by the bed-bug, flea, mosquito and other blood-sucking insects. Recently

Napier and his associates have demonstrated the transmission of kala-azar by *Phlebotomus argentipes*, and according to other investigators the disease, in China, is transmitted by a sandfly, *P. major*'. The first sentence, which the reader will naturally accept as the considered opinion of the writers, is a surprising one and it is doubtful if the belief is shared by anyone outside the University of Pennsylvania. The rest of his chapter is hardly more satisfactory; under the heading of treatment a statement made by the reviewer in 1924 is quoted and all the very important work that has been done since that date is entirely ignored.

The reviewer was somewhat discouraged by his first attempt, but he felt that it was unfair to judge the book on its treatment of one disease when it was possible that neither author had been within five thousand miles of the countries where this disease is endemic. He turned more hopefully to yellow fever as he noticed that one of the authors had been a pathologist in a hospital in Panama, but here he found no improvement; except for the statement that the disease is caused by a filtrable virus, there is scarcely a sentence in the section that could not have been written when King Edward the Seventh was on the throne of England. It is definitely stated that there is no personal prophylactic measure that is of any value, but it is naively suggested that as a general measure of prophylaxis yellow fever infected areas should be avoided; mosquito control is however mentioned.

In this same chapter, 'Diseases due to Filtrable Viruses', Oroya fever and, surprisingly, blackwater fever are included. No attempt is made to justify the inclusion of the last-named in this section and the subject is discussed in an orthodox manner with the necessary emphasis on malaria in the ætiology. There is one point however that calls for comment; in the middle of page 315 appears the following sentence:—'It is remarkable that an important disease, such as black-water fever was not recognized until recently. Lebean, about 1850, first described the disease in Magagascari'. Further down the page, against the quinine theory of the ætiology of blackwater fever, the following argument is used:—'Furthermore, blackwater fever must have been prevalent in Europe long before the introduction of cinchona bark on the continent'. Cinchona was introduced into Europe in 1632!

In the malaria section both atabrine and plasmochin are mentioned. The authors refer to the latter as if it were a substitute for quinine and condemn it as such, quoting some of the platitudes and cheap gibes that have emanated from others who have similarly failed to understand the properties of this drug, such as 'the need to combine quinine with plasmochin points its own moral' and 'advocates of plasmochin appear to fail to realize that the gametes [sic] or crescents also disappear eventually under quinine treatment'. 'Eventually' is a comprehensive word; but the authors of this book 'appear to have failed to realize' that quinine has no direct action at all on the gametocytes of *Plasmodium falciparum*, and that plasmochin without any quinine will cause their disappearance in 48 hours or less in nearly every instance.

No attempt is made to link up typhus fever with either Rocky Mountain fever or tsutsugamushi disease, nor, although the flea is mentioned as a possible transmitter of typhus, to differentiate epidemic louse-borne typhus and endemic flea-borne typhus (or Brill's disease). In the typhus section under the heading of diagnosis the statement is made that 'the Weil-Felix reaction—is believed not to be specific'. The statement will not be of much help to the student, and, if it conveys anything, it conveys the impression that the test is of no value in the diagnosis of this disease, whereas actually it is of very great value.

The whole book gives the impression of having been compiled from other textbooks and these not the most recent editions. Surely there are medical libraries in the University of Pennsylvania that take in journals, such as the *Tropical Diseases Bulletin*! In nearly every

section there is some very useful information well summarized, but intermingled with this there are so many misleading statements that the book will be of little value to anyone.

L. E. N.

AIDS TO MEDICINE.—By James L. Livingstone, M.D. Fifth Edition. 1935. Baillière, Tindall and Cox, London. Pp. viii plus 422. Price, 5s.

It is always a moot question how far books of the 'cram' variety should be encouraged; the answer is, that it depends partly on the book but mainly on how it is used and on the person who uses it. If the student uses it as his textbook, he may get through his examinations, but he will acquire a very imperfect knowledge of his subject; this is perhaps a greater indictment of the examination system than of cram books in general.

One can always rely upon the 'Aids' series books; one knows that at least the subject-matter will be accurate and reasonably up to date. We say 'reasonably' because of course it is essential that recent work that has not been generally accepted should not be included in a book of this kind, however certain the author may feel that in time it will be accepted.

This particular volume is no exception. Nearly all the sections that we read have obviously been revised recently. For example in the section on anæmia a classification on the lines of that suggested by Janet Vaughan has been introduced; but we cannot quite agree that the extrinsic factor is vitamin B₁₂. Recent work has shown that it is *not* identical with B₁₂, though it is associated with the vitamin B complex in many foodstuffs.

Even the sections on tropical medicine are far more up to date than they are in many textbooks on general medicine. In the malaria section atebirin and plasmodin are mentioned, though not pressed; this is as it should be. We were a little disappointed that tartar emetic is the only drug advocated for kala-azar, but if we were asked to write the treatment for black-water fever in one line, we do not feel that we could improve on 'Bed: warmth: fluids *ad lib.*; withhold quinine'.

It is a book that we can recommend to the student, and we believe that many practitioners would find it useful to aid their memory.

L. E. N.

FOOD AND BEVERAGE ANALYSIS.—By M. A. Bridges, B.S., M.D., F.A.C.P. 1935. Henry Kimpton, London. Pp. 246. Price, 16s.

IN 1933 Dr. Bridges wrote a book, *Dietetics for the Clinician*. A second edition was demanded in 1935. Both the first and the second editions of this book were reviewed favourably in this journal. The present volume is by way of being a supplement to this book. It consists mainly of tables relating to food values and allied subjects.

The main bulk of the book is taken up with a table that covers 117 pages, giving the nutritive—protein, fat and carbohydrate—and caloric values of some three thousand food substances. The system of giving the foods in terms of average portions is adopted; this facilitates easy calculation of a diet; however, at the same time the percentage occurrence of each element is given so that the food value of any definite weight of a substance can be worked out quickly.

Many of the substances in this table are proprietary food preparations and of course there are few of the common Indian foods; nevertheless, the table will be very useful to the worker in India, until such time as a similar table of Indian food substances has been prepared. Such a book cannot be expected for some years, as only a small proportion of the foods have so far been analysed.

Another table gives the mineral content of about 500 foods, and a third the vitamin content of a slightly smaller number. There are other useful tables, such

as those giving the average weight of children and adults of different ages and heights.

The tables are presented with introductory pages giving fundamental facts and very valuable information on the subject of dietetics. Certain figures that are quoted cannot of course be accepted for use in this country; for example, 100 grammes of protein is seldom included in the daily ration in India, though it is possible that it might be with advantage; on the other hand, it is doubtful if 150 grammes of fat would not be too much. However the author is never dogmatic and frequently points out that climate and other factors must always be taken into consideration.

The book is a very valuable and important contribution to the literature on dietetics.

L. E. N.

INFANT NUTRITION: A TEXTBOOK OF INFANT FEEDING FOR STUDENTS AND PRACTITIONERS OF MEDICINE.—By W. McKim Marriott, B.S., M.D. Second Edition. 1935. The C. V. Mosby Company, St. Louis. Pp. 431. Illustrated. Price, \$4.50

THIS book is written for the medical practitioner and student rather than for the sanitarian, the nurse, and child-welfare worker, though of course there is much information that the intelligent nurse will find useful. The ground covered by this book is usually included in any textbook on children's diseases, but here the subject is dealt with in more detail, and then again it is a subject which is undergoing such rapid changes that most practitioners will find this book a useful supplement to their textbooks.

This is a second edition of a book that was first published five years ago, but most of the sections have been completely rewritten, we are told in the preface and we can well believe it, as they all appear to be completely up to date.

The first chapter is on growth and development with charts and tables showing the average weight and the rate of increase of normal infants during the first year of life. Then follow chapters on the metabolism of different food substances which will be found very useful to those who have forgotten their physiology or whose knowledge is out of date. There is a good chapter on the vitamins and the conditions associated with their deficiency. Later chapters are on breast feeding, on artificial feeding, on the composition and character of cow's milk, on dried milks, on acid milks, and so on.

The second half of the book is devoted to different chapters on abnormal conditions, such as malnutrition, diarrhoea, coeliac disease, vomiting, constipation, prematurity, deficiency diseases such as rickets and scurvy, and common infections; in all those conditions diet plays an important part, both in the ætiology and in the treatment.

It is a book that we can thoroughly recommend to the pædiatrician and to the general practitioner.

THE TREATMENT OF DIABETES MELLITUS.—By Elliott P. Joslin, M.A. (Yale), M.D. (Harvard). Fifth Edition. 1935. Henry Kimpton, London. Pp. 620. Illustrated. Price, 28s.

LITTLE comment is necessary on the fifth edition of Professor Joslin's excellent treatise on the treatment of diabetes mellitus. It has always been a standard book of reference and in the present edition it fully justifies the claim.

The present edition has been revised and partly rewritten, some of the unimportant portions being omitted. Great stress has been laid on the ætiology and the prevention of diabetes which has been fully discussed in chapter III.

Chapter V dealing with the pathology and causes of death in diabetes has been written in collaboration with Drs. Warren and Root and contains very useful information and data which will amply repay perusal, so also chapter XXII dealing with surgery and diabetes.

The incidence of cardiovascular diseases in relation to diabetes has also been very ably discussed.

Chapter XXIV dealing with the subject of diabetes in children (and written, in collaboration with Dr. Priscilla White) is one of the most important and useful portions of the book.

The book on the whole contains a mine of useful information, being the product of Professor Joslin's life-long and intensive study of the problem of diabetes. It is a standard work which we feel sure will prove invaluable to practitioners and students all over the world.

J. P. B.

PRACTICAL ENDOCRINOLOGY: SYMPTOMS AND TREATMENT.—By M. A. Goldzieher, M.D. 1935. D. Appleton-Century Company Incorporated, New York and London. Pp. xxii plus 326. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 15-12

THIS is a book written in simple language for the benefit of the practising physician. Non-essentials have been omitted with the result that reference to any special point or syndrome is greatly facilitated.

The book begins with a short chapter on the morphology of the various endocrine glands, and the second chapter is devoted to a clear and concise account of their physiological action. This is followed by advice as to how a patient suffering from endocrine disease should be investigated and a description of the various laboratory procedures and tests that should be employed.

The major portion of the book is devoted to descriptions of the clinical characteristics of gland disorders, which will be found more useful to the practitioner than the usual method of describing the symptoms under the heading of the gland concerned, for in this book he is presented with the clinical appearance and reactions of the patient and then informed which gland or glands are usually affected.

Treatment is given at the end and is described under eighteen different headings which indicate the gland or glands at fault.

It is a thoroughly practical book and one that will be found useful for the general practitioner in assisting him to diagnose and treat successfully the obscure and not-yet-fully-understood diseases that arise from dysfunction of the endocrine glands.

If a criticism may be offered it is that the complete omission of all references is rather unusual and in this instance, when the author admits all his views are not generally approved of, it is perhaps rather unfair to other workers. This deficiency is offset by the claim that the considered views of an experienced worker in a difficult subject will be found of more use to the inexperienced physician than a discussion of the *pros* and *cons* from which he will have to make his own choice. This may be sound reasoning, but what is to happen to the physician who relies on this book and is faced with failure in a case after he has followed its precepts? It is felt he might have been given the opportunity of seeking for further knowledge elsewhere, by the inclusion of a few references to larger books.

REPORTS ON CHRONIC RHEUMATIC DISEASES BEING THE ANNUAL REPORT OF THE BRITISH COMMITTEE ON CHRONIC RHEUMATIC DISEASES APPOINTED BY THE ROYAL COLLEGE OF PHYSICIANS. NO. I.—Edited by C. W. Buckley, M.D., F.R.C.P. 1935. H. K. Lewis and Company, Limited, London. Pp. x plus 159. Illustrated. Price, 12s. 6d.

TEN years ago it would have been impossible to refute the accusation that chronic rheumatism was a very neglected subject in Great Britain. During the last decade, however, the medical profession in that country has become more and more 'rheumatism

conscious'. The estimation made by the Ministry of Health that this disease alone costs the country over £17,000,000 per annum for industrial incapacity undoubtedly had a stimulating effect. One of the early signs of this increased interest in rheumatism was the establishment of the Red Cross rheumatism clinic in Peto Place and a more recent one is the appointment of a British Committee on Chronic Rheumatism by the Royal College of Physicians, with Sir Humphry Rolleston as chairman, a very representative body of members, including Lord Horder and Lord Dawson of Penn—the President of the College, and Dr. Copeman as secretary.

This book contains a foreword by the chairman, a note on the origin and work of the committee, a report of the nomenclature sub-committee, and a number of papers on chronic rheumatism in its different aspects, such as allergy and hypersensitiveness, biochemical investigations, focal sepsis, and histamin in the treatment of rheumatism.

The nomenclature report does not sound very practical, but the practitioner will find even this very instructive and from it he will learn much regarding the aetiology and symptomatology of the different types of rheumatism.

Rheumatism is not yet looked upon as one of the serious diseases of this country; this is possibly because its importance is overshadowed by other more acute and more easily preventable diseases. Most physicians, however, have some examples of chronic rheumatism in their practices, and this authoritative book should certainly find a place in medical libraries of any standing in India.

RÖNTGENOLOGY: THE BORDERLANDS OF THE NORMAL AND EARLY PATHOLOGICAL IN THE SKIAGRAM.—By A. Köhler, Prof. Dr. med., Wiesbaden. Second English Edition revised by the Author. Translated and Edited by A. Turnbull, M.A., B.Sc., M.B., Ch.B. (Glas.). 1935. Baillière, Tindall and Cox, London. Pp. xvi plus 681, with over 400 illustrations. Price, 50s.

THIS is the second English edition of a world-renowned textbook on röntgenology. It is probably no exaggeration to say that it is the best-known and most authoritative general book on the subject in any language, and it has been translated into a number. There have been six German editions of which the first was published in 1910.

The suggestion is made in the author's preface that the aims of the book are rather different from those of the ordinary handbook on the subject, that is, that he has endeavoured to demonstrate by pictures, as well as by discussion in the text, the slight departures from normal detectable by röntgenographical examination which usually indicate the earlier signs of disease, rather than to show the gross divergences from normal which are more usually associated with advanced disease. Whilst admitting that the author has achieved his object very well indeed, we would point out that this surely should be the aim of all writers of handbooks that are meant to guide the practitioner, though for the student entering upon the practical part of his professional training it is perhaps advisable that he should be shown extreme instances in order that he may more easily obtain a visual impression of the whole disease process. We say that it should be the aim of all handbooks, but we quite admit that it is a common fault of writers on many subjects to portray, not only the last stages of a disease but even the extreme examples that are rarely seen in actual experience.

The author has avoided all specialist and all 'experimental' röntgenography and has confined himself to practices that are the daily routine of any röntgenological department attached to a general hospital; these are of course varied and numerous; he implies that when some of these more specialized procedures, such as ventriculography for example, are firmly established, they may be included in future

editions; others that he considers of doubtful usefulness he foretells will disappear from usage.

All the sections in the book appear to be good, but those on the stomach and intestines are particularly so; the descriptions are clear and adequately illustrated. There is not the excess of illustrations that are often just thrown at the reader without any particular selection having been exercised—probably put in because they happened to be in the author's collection—but each illustrates some point and often a number of points. Furthermore, the illustrations are not those superlatively clear ones that can only be produced with the most up-to-date and powerful apparatus, but they are of the clarity that we in India can usually achieve with the apparatus available in the larger hospitals here. The author says that most of the skiagrams have been taken with a twelve-year-old apparatus.

The translation has been a very literal one, and the language is in places very stilted and sometimes actually difficult to follow for this reason. Unnecessarily technical words are used; they are all words that can be found in the medical dictionary, but they could often have been replaced by words of everyday conversation without loss of precision. Surely it is unnecessary to say *anamnesis* when *history* is meant.

The author is not dogmatic and makes it quite clear that the röntgenological findings should be considered in conjunction with the history and the rest of the clinical findings; in some cases more importance will be attached to the röntgenological findings, in others less, but never should they be considered alone, or allowed to override definite contrary clinical findings.

Any physician who has to read röntgenograms will find an authoritative book of this kind almost essential, and we know no other that will serve his purpose so well.

THE SPLEEN AND RESISTANCE.—By D. Perla, M.D., and J. Marmorston, M.D. 1935. Baillière, Tindall and Cox, London. Pp. xi plus 170. Price, 9s.

A GREAT deal of work has been done on the spleen during the last decade, but there still remains very much to be found out about it. It is difficult to explain why it is that in lower animals it seems an essential organ to protect them from the effect of certain infections, such as *Bartonella* in mice and *Plasmodium* in monkeys, and yet man can apparently get on quite well without his spleen.

Much of the recent work has been summarized and reviewed in this book. It is concluded with a very useful résumé of the subject; it is useful, but disappointing (through no fault of the writer), as, although we know a great deal about the spleen, we do not yet know the fundamental facts.

There is no reference to the recent work on monkey *Plasmodium* in India, though it has a very definite bearing on the subject, and in the list of 447 references some of the most important work done in England has not been included. Nevertheless, it is a valuable contribution to the literature on the spleen.

HIGH BLOOD PRESSURE AND ITS COMMON SEQUELÆ.—By Hugh O. Gunewardene, M.B., B.S. (Lond.), D.M.R.E. (Cantab.). 1935. Baillière, Tindall and Cox, London. Pp. xi plus 172. Illustrated. Price, 7s. 6d.

THIS small book has been written to encourage the study of high blood pressure by the general practitioner. The observations recorded here are those made on 250 cases studied outside the hospital. In the first chapter the author rightly insists on the importance of the diastolic pressure as a true index of hypertension, and considers a diastolic of 90 and a systolic of 150 as upper limits of the normal for an adult. In the second chapter he ascribes hypertension as the commonest cause of heart disease. The third chapter is devoted

to the method of determining blood pressure; he rightly advocates the use of a mercurial instrument with a scale reading up to 300 and discards the aneroid machines. The systolic pressure is first roughly obtained by the palpation method, then the bag is deflated till the first click is heard. An illustration of the various subsequent phases has been given. In nearly all cases the point of disappearance of all sounds is 5 to 10 mm. below the actual diastolic, so that, if the latter number is added to the figure at the point of disappearance of sounds, a relatively accurate diastolic pressure is obtained when the different phases cannot be easily determined by the ear.

In the fourth chapter the author briefly describes the clinical types, with photographs, though of course appearances are not reliable. Following Clifford Allbutt he considers arterial hypertension under two main headings, the renal and hyperpietic, and finds non-renal hypertension rare under 30 years of age. From his clinical observations on the influence of occupation and living Dr. Gunewardene is of opinion that sedentary habits and overfeeding are chiefly responsible for essential hypertension, with heredity and diathesis only playing a subsidiary part in some. The normal pressure-regulating mechanism of the body is deranged in this condition, possibly by a dysfunction of the liver. The next part deals with the sequelæ of high blood pressure which usually involves the heart, the kidney, or the brain, or all. The author differentiates essential hypertension from chronic nephritis, in a tabular form. The influence of syphilis has been referred to; it plays little or no part in raising blood pressure.

Chapter IX deals with the occurrence of strokes which have been divided into two groups, motor and sensory. The author states that cerebral hæmorrhage does not occur with diastolic pressure of under 115 and advises the prognosis accordingly. This statement however requires confirmation. Chapter XV contains an account of acute œdema of the lungs. Apart from mechanical and inflammatory causes it is said to be the result of left ventricular fatigue under persistent hypertension. The prognosis has been discussed in chapter XVI and a table showing the causes of death in hypertension has been given. In the last chapter, on treatment, the author refers to general principles regarding rest, exercise, diet, septic focus, etc., in brief and agrees with the oft-repeated statement that drugs are not of much value, but he uses the sedatives and vasodilators when necessary. He has used patent medicines extensively, none of which proved more than financial burdens to the patients. He has obtained some good results by electrotherapy in selected cases. He believes that all cases of hypertension require treatment. There is an appendix showing a form used in the investigations of the cases, followed by an adequate index. Cross references throughout the text make reference simple and rapid.

R. C.

APHASIA—A CLINICAL AND PSYCHOLOGICAL STUDY.—By Theodore Welsenburg, M.D., and Katherine E. McBride, Ph.D. 1935. The Commonwealth Fund, New York. Pp. xvi plus 634. Illustrated. Price, 21s. Obtainable from Oxford University Press, Bombay and London

THIS book embodies the results of the most extensive study of aphasia ever undertaken and will long remain the standard work of reference on the subject in the English language, if not in any language. The authors' records cover the examination of 234 cases and an additional investigation of a further 80 cases. The 234 cases include (1) 60 cases of aphasia, (2) 22 cases of unilateral cerebral lesion without aphasia, and (3) 85 'normal' adults, i.e., selected hospital patients suffering from bone fractures, dislocations, hernia, arthritis and similar surgical conditions. This extensive and accurate employment of 'controls' is one of the main features of the book which gives it great value to the clinician as well as to the psychologist. The

aphasic group includes vascular, tumour and traumatic cases. The patients themselves were drawn from a wide variety of educational and occupational levels. The 'normal' controls represent a good sample of the average population.

For the selection of the subjects of the study, the following criteria were laid down:

1. They must be under sixty years of age so as to reduce the possibility of a picture complicated by senile changes.

2. The aphasic and the control cases of unilateral cerebral lesion without aphasia must not show any signs of a disorder known to affect mental functioning, e.g., psychosis; general paralysis, advanced cerebral arteriosclerosis; the 'normal' controls must likewise be free from any disorder known to affect mental functioning and they must also be free from any neurological disturbance.

3. All patients must have been English-speaking by birth.

4. They must have adequate sight and hearing.

The tests employed were for the most part the mental and educational achievement tests found useful for children. The typical adult performance of these tests was determined and then the aphasic responses were interpreted in terms of the normal adult performances. As there are no tests of language which do not depend on intellectual ability, the intellectual level of each aphasic tested was carefully taken into account.

In view of the complexity and variations of aphasic disorders, it was essential to have tests which provide for an examination of all the performances which may be affected. It was also necessary to provide tests for the detailed study of particular disturbances as well as tests to study the relative importance of specific speech defect along with other changes, i.e., the patient's method of work. The authors conclude that the most satisfactory classification of types of aphasia is not a logical but an empirical one. Hence they class the disorders in four main groups designated by the descriptive terms, 'expressive', 'receptive', 'expressive-receptive', and 'amnesic'.

The disturbances characteristic of the predominantly expressive disorder may appear in any degree of severity from a slightly abbreviated speech with occasional mispronunciations to an almost complete loss of all forms of spoken response. Cases of the predominantly receptive group show different degrees of limitation in the understanding of spoken language, differences extending from failure to appreciate the full significance of the verbal formulation down to a faulty understanding of single words or short sentences with some difficulty in perceiving the word-sound.

Patients with the expressive-receptive disorder are characterized by their serious limitations in all language performances since all language processes are so defective that no distinction can be made between the expressive and the receptive. The amnesic disorder consists essentially of a difficulty in evoking words as names for objects, conditions or qualities. The speech in amnesic aphasia, therefore, consists largely of familiar and colloquial expressions and of emotional and automatic responses.

In regard to the nature of all aphasic disorders, the conclusion reached by the authors is that although first and foremost a disorder of language, it is not limited to the language processes since it is shown to involve changes in the patient's reactions to practical, everyday problems and to matters of social response and relationship. As regards the seat of the lesions, certain definite statements can be made. First, the lesion must be within a given area, which includes both the anterior and the posterior part of the brain. By the anterior part is meant the pre-central convolution and the adjacent parts of the frontal lobe, the pre-motor area. The posterior part includes the inferior portions of the post-central and parietal lobes, the superior part of the temporal lobe, and the anterior part of the occipital. How much of the subcortex is involved it is impossible to say.

In the portion of the book dedicated to a historical survey of aphasia, the authors pay tribute to the outstanding contribution to the subject made by Hughlings Jackson, whose statement that, 'to locate the damage which destroys speech and to locate speech are two different things', is just as true to-day as it was seventy years ago.

The book is provided with a copious bibliography and a good index.

O. B-H.

INCOMPATIBILITY IN PRESCRIPTIONS AND HOW TO AVOID IT—WITH A DICTIONARY OF INCOMPATIBILITIES.—By Thomas Stephenson, D.Sc., Ph.C., F.R.S.E., F.C.S. Fourth Edition. 1935. The Prescriber Offices, Edinburgh. Pp. vii plus 62. Price, 6s.

DIFFICULTIES are sometimes experienced by both students and junior practitioners in writing prescriptions for patients in general practice; information in general books on materia medica is often too scanty to help them. Long association with students of pharmacy and chemistry has enabled Dr. Stephenson to write the present treatise in a most concise and lucid way, making it a most useful and practical guide for physicians who would avoid the many pitfalls encountered in prescribing. The present volume is nearly double the size of the original volume, and is thoroughly revised and brought up to date, and is strictly in accordance with the *British Pharmacopœia* of 1932 and the *British Pharmaceutical Codex* of 1934.

The first part of the book is devoted to the general principles of incompatibility and the second part is an invaluable addition consisting of the dictionary of incompatibilities dealing with both the official and non-official drugs, their doses, solubilities and incompatibilities. The book is well got up, handy and can be confidently recommended to those for whom it is intended.

R. N. C.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY.—By Hamilton Bailey, F.R.C.S. (Eng.). Fifth Edition. Revised. 1935. John Wright and Sons Limited, Bristol. Pp. xii plus 287, with 341 illustrations, some of which are in colour. Price, 24s.

MR. HAMILTON BAILEY'S excellent little book on physical signs in clinical surgery has reached its fifth edition, and this is a fact which speaks for itself.

Though the book contains a few more pages than the previous editions, the author has resisted the temptation to enlarge it to any great extent. The increase in the number of pages being due for the most part to the addition of a few illustrations. Practically all the recognized signs used in clinical surgery are mentioned and most of them are admirably illustrated. The descriptions are brief, but at the same time lucid and quite sufficient to be clearly understood by the reader.

It is undoubtedly one of the best of the smaller works and should be in the possession of every student of medicine and surgery.

H. E. M.

MARTINI'S PRINCIPLES AND PRACTICE OF PHYSICAL DIAGNOSIS.—Edited by Robert F. Loeb, M.D. From the authorized translation by G. J. Farber, M.D. 1935. J. B. Lippincott Company, Philadelphia and London. Pp. xviii plus 213 with 30 illustrations in the text. Price, 9s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 6-12

'THIS little book, starting to-day on its way to those who intend to become physicians', are the opening words of the author's preface, and we would like to continue 'has fallen into the hands of one who, whilst suffering under the delusion that he has been a

physician for twenty odd years, has found much in it that he had forgotten or that he never knew'.

Innumerable books on physical diagnosis have been published, some too large, some too small, some too abstruse, some irritatingly simple, and many very satisfactory indeed; we will class this with the last group, without making any further invidious comparisons.

The scope of the book is the usual one, the diagnosis by the use of the eyes, ears, and fingers, unaided by any instrument other than the stethoscope, of disease conditions in the chest and abdomen. Within its scope the book is comprehensive, the subject is clearly and concisely presented, and it is in the form of a compact and strongly-bound volume, very suitable for the student's pocket. It is a book that we can strongly recommend.

THE NERVOUS PATIENT: A FRONTIER OF INTERNAL MEDICINE.—By Charles P. Emerson, M.D. 1935. J. B. Lippincott Company, Philadelphia and London. Pp. xiii plus 453. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 13-8

THE author has aimed at producing a reference book for general practitioners in this important side of their work and has succeeded admirably in his task. The writer is a physician and not an alienist and is at his best when describing the psychological manifestations of physical disease. The field he has attempted to cover is a wide one but he has touched upon most aspects of it, and has given, if not a profound study of the subject, a very practical discussion. This book should prove of great use to the practitioner.

Abstracts from Reports

ANNUAL REPORT OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA FOR 1933. VOLUME I. ON THE STATE OF THE PUBLIC HEALTH IN BRITISH INDIA AND SOME INDIAN STATES

[Continued from last issue, p. 115]

MATERNITY AND CHILD WELFARE

Maternity mortality.—Some idea of the causes of death may be gathered from the reports of certain hospitals for women summarized in the *Journal of the Association for Medical Women in India* (August 1934). The figures relate to the year 1933. The rate of death per 1,000 cases admitted in these hospitals was 24 per mensem. That for the Government Hospital for Women and Children, Madras, was 22. For comparative purposes the statistics of the St. Mary's Hospital, Manchester, are shown along with these figures. The death rate in Manchester was 9 per thousand cases. The rate would naturally be less in England even among cases admitted to hospitals. What is significant is the cause of the great proportion of the deaths in India compared with those at Manchester. Anæmia, eclampsia and puerperal sepsis account for deaths in a manner out of all proportion to these causes in the English figures. Hæmorrhages are the next most potent cause of loss of life. These deaths are in the majority of cases preventable and could be prevented if India had an adequate maternity service. Even in the capital city where there are three good women's hospitals and a large number of trained midwives and health visitors, the reported deaths from sepsis were 18 and those from eclampsia 10. In the city of Madras, boasting one of the finest maternity hospitals in the world besides several other good hospitals for women, the maternal mortality rate was 12 per 1,000 and 54 per cent of these deaths were said to be due to puerperal sepsis. In the city of Bombay 45 per cent of deliveries are conducted in hospital and 24 per cent by qualified nurses, leaving only 29 per cent to be attended by unqualified persons. The maternal mortality for the city is 8 per thousand. The figure for Calcutta is not available, but since fewer deliveries take place in that city than in either Madras or Bombay the probability is that there it is even higher.

In view of the absence of reliable statistics, it is impossible to state how many women in India die yearly during child-birth, but the number must be nearly one and a half lakhs, excluding deaths from complications of abortion which would swell the number still further. An epidemic disease assuming these proportions demands and receives attention from local authorities, health departments and the public itself. Deaths of women from preventable causes do not appear to receive the same attention. The explanation may

be partly that the facts are not known sufficiently, partly because mortality from child-bearing does not occur in epidemic form, but it must also be due to the too commonly held view that it is inevitable that some women must die during child-birth. 'Some women' in each area naturally become thousands when applied to the whole of India.

Maternity work and midwives training.—The maternal mortality rate is not likely to be reduced to any extent until the maternity service is improved. The problems involved in securing such improvement have been mentioned each year in this report, and the position does not seem to alter materially from year to year. Over a space of time, however, it is evident that slow progress has been made. The number of women who go to hospitals for delivery has certainly much increased, the Bombay figures being particularly striking. In urban areas, accommodation for maternity cases is often insufficient to meet the demands made on existing hospitals. Maternity homes, especially in Western India, are springing up. In towns also the services of trained midwives are in greater demand. This is so far satisfactory, but could the pace not be accelerated? With regard to urban areas it certainly could be. Municipal committees have the power and the opportunity to make advance and keen medical officers of health should stimulate their councils and committees to wipe out the disgrace of unnecessary loss of life occurring daily in the cities and towns of India. It seems possible that progress could be made in the following ways:

(i) The greater number of trained midwives now available makes it possible for committees to be stricter than formerly as to the qualifications of those practising in a given area. There is no longer any valid reason why women practising midwifery in the towns should not be forced to undergo training within a limited period of time.

(ii) A necessary concomitant of such action would be the keeping of a register of all midwives practising in the area, with ability to take action against those not registered.

(iii) A better class of women should be trained. The present economic situation in India is forcing women of the middle classes to take up gainful occupations and in various places they are offering for training.

(iv) In many places municipalities are already employing their own midwives. This service is capable of much extension and development. It ensures, or ought to ensure, good service for the public and a decent livelihood for the midwife. Such midwives should be whole-time salaried workers and fees should be recovered for their services from all who can afford to pay.

(v) One means of securing a good service is to have supervision of midwives. This can be effected by means of special posts as midwifery supervisors, or it can be done by means of health visitors. For good midwifery practice supervision is absolutely necessary.

(vi) In places where maternity homes exist, these should also be supervised to ensure that proper standards are maintained. Minimum standards should be enforced for such homes; these will safeguard the lives of the patients.

(vii) Antenatal work should be encouraged and in fact insisted upon at all welfare centres, hospitals or maternity homes maintained or assisted by municipalities.

(viii) An investigation of maternal deaths would assist in planning for improved service and measures to reduce maternal mortality.

These suggestions are perfectly feasible for many cities and towns and only courage is needed to put them into practice. It is realized, however, that any municipal committee must carry its community with it in initiating such reforms. The futility of providing a service for people who do not know how to use it and are not ready for it has been amply demonstrated.

When examination of the position in rural areas is made, the difficulties are found to be much greater. The villages are still in the clutch of the indigenous *dai*; necessarily so, since she is the only person who is available for help. It is urgently necessary to plan something for rural India, however, for approximately nine times as many children are born in villages as in towns in India. At present nature sees to it that normal cases mostly recover, though the morbidity through bad midwifery and subsequent lack of nursing care can only be guessed at. In abnormal cases the patients die, sometimes undelivered, of sepsis or shock, or, if distances permit, they are taken into headquarters hospitals, usually too late. Nowadays one hears a great deal of talk of rural uplift and women's needs have not been altogether neglected in these plans, but this problem of maternity work in rural cases has nowhere been attacked with the vigour it deserves. Schemes for giving village *daïs* a few weeks' experience in a hospital or lectures by medical men without any practical work will never meet the need.

Child welfare work.—It is now nearly twenty years since the first child welfare centres were started in India, and it may be useful to take stock of the present position. This work was introduced into India as a result of the example set in Europe without a great deal of reflection as to whether conditions in India were ripe for such a movement. In some ways they certainly were not. For example, the demand for cure or treatment was not satisfied as it apparently must be before preventive work has much chance of success. Furthermore, the raw material in the shape of nurses, or young women ready to be trained as such, needed to implement child welfare schemes, was not ready to hand. These were two major difficulties. Others were—a certain amount of ignorance and misunderstanding on the part of medical practitioners who had not watched the evolution of the movement in the West, the almost complete ignorance of the general public, hampering social customs such as early marriage and 'purdah' and the profound illiteracy among the women of India. Perhaps it was as well that the early pioneers did not stop to think of the difficulties in their path or they might never have started at all. These obstacles to the development of the work still exist, but, in spite of them, the number of centres has increased and there is a general appreciation of their usefulness even though the exact sphere of this usefulness is often imperfectly understood. Provinces such as the North-West Frontier Province and Assam are at the beginning of their child welfare career for in such provinces medical and maternity needs are still far from adequate. In other provinces, the movement is thoroughly established and is coming to be regarded as an essential part of public health work. The part played by the provincial

governments in the furtherance of child welfare work varies enormously.

The appointment of medical women officers as assistants to the Directors of Public Health is what is required to develop maternity and child welfare work adequately in every province. Child welfare work is best where there is provincial control and poorest where there is none. The fact that some provinces are providing funds and personnel and even training schools shows that they think this is a desirable form of public health expenditure. Others are apparently of a different opinion, but there can be no doubt of the correct course.

Health visitors and health training.—A rough computation of the number of health visitors working in India would give a figure of about 300—that is less than one per million of the population. In some centres, the ineffective system of employing nurses and midwives as health visitors is still in vogue. The provinces which employ the greatest number of health visitors are the Punjab, the Central Provinces and Delhi. The two former provinces have for some years had health schools which are financed by the provincial governments concerned. The presence of a training school and the number of welfare centres and health visitors employed are circumstances which are always closely connected. If a province is intent on work of this kind, it finds it necessary to provide a school for training workers. It is therefore no accident that the two provinces which have their own training schools should have the greatest number of health visitors. Nor is it accidental that the Presidencies of Bengal and Bombay, which have never supported the schools which voluntary societies have established, should be poorly supplied with health visitors. The Madras Presidency has a school which is supported mainly by the Indian Red Cross Society, but it is now receiving a Government grant. Burma is hoping to start a school of its own in the near future. The Lady Reading Health School at Delhi continues to be an All-India Institute and it is hoped that in the course of time it may undertake the training of a superior grade of workers as indicated in the report of the previous year.

Vaccination against smallpox.—Once more, because of the higher incidence of smallpox, vaccination operations in British India increased from 20,587,799 in 1932-33 to 22,143,370. The increase of 1,639,392 revaccinations was almost wholly due to the large increases under this head in the Madras Presidency (1,902,368) and in Burma (117,150). Of the 9,678,876 registered infants only 43 per cent were successfully protected. Nearly 97 per cent of the primary and 51 per cent of the revaccinations were recorded as successes.

MEDICAL RESEARCH

The Indian Research Fund Association, in spite of the continued 'cut' in its grants from the Government of India, has courageously proceeded with most of its larger and more important enquiries and has not hesitated to draw further from its invested capital in order to maintain the programme of research which its Scientific Advisory Board and Governing Body have considered essential. It has not, of course, been possible to find money sufficient to finance all the enquiries which might have received support in happier circumstances, but on the whole there has been less curtailment in research than in other medical and public health fields of activity and it is only fair to state that nothing of first importance has been eliminated. The Indian Research Fund Association has indeed sanctioned an expanded programme of research on cholera and, whilst the proposed cholera commission has not been instituted, the various enquiries connected with this disease and its causative organism have been co-ordinated by means of a cholera advisory committee whose function is to control a planned scheme of research without interfering with the personal initiative

and individuality of the different workers. Past experience, indeed, has shown that team work is essential if success is to be achieved in the investigation of a subject like cholera which possesses so many inherently different aspects and recent results have fully corroborated that experience. Important progress has already been made and there is every hope that considerable light will be thrown upon a number of the many problems associated with this disease. Further investigations on the cholera bacteriophage both in the field and in hospital have been included in the research programme in order, if possible, to reach definite conclusions as to the value of this 'entity' in the prevention and treatment of the disease. This branch of cholera research has now been in progress in India for over 6 years and, whatever the eventual verdict may be, no one can deny that every effort has been made to assess correctly the part which cholera bacteriophage may play in the control of this epidemic disease.

The Malaria Survey of India is still entirely financed by the Indian Research Fund Association and whilst the annual grants for the maintenance of that organization constitute a considerable percentage of the annual budgets of the association, the cost is minute in relation to the immensity of the malaria problems of this country and there can be no doubt that India obtains full value for the expenditure incurred. Whilst the malaria survey has not yet become an integral part of the Government of India's Public Health Organization, in actual practice it functions as such and the advice and services of its officers are always at the free disposal of central and local administrations in connection with malarial problems.

Nutritional research continues to occupy an important place in the programme sanctioned by the Indian Research Fund Association and at the laboratories at Coonoor, till recently under the direction of Major-General McCarrison, a whole series of important departments have been developed. As in other fields of research, additional lines of work have been gradually evolved and it is almost impossible to envisage what the future may have to give from these developments. Fortunately for India, the Governing Body of the Indian Research Fund Association has never failed to realize the importance of this branch of medical research and whilst there seems no immediate prospect of establishing an institute of nutrition such as already exists in many other countries, the basic requirements for progress have been satisfactorily provided in the Coonoor laboratories. A further desirable extension of the work has recently been sanctioned by the Indian Research Fund Association and plans are now being made for a comprehensive survey of the nutritive values of the common food-stuffs of the different provinces of India.

It is obviously impossible even to enumerate the different research enquiries now being carried out under the auspices of the Indian Research Fund Association and if a few of the more important have been given specific mention, that must not be taken to imply that the others are not of importance. For more detailed descriptions of these enquiries reference must be made to the report of the Scientific Advisory Board and to the *Indian Journal of Medical Research* and the *Records of the Malaria Survey*, the two journals published under the auspices of the association. In addition, a considerable amount of valuable research work is also being carried out by various departments of the medical colleges situated in different parts of India.

[This abstract, which has extended over three issues of the *Gazette*, is quite inadequate as a complete résumé of this valuable report, because complete sections have been entirely ignored. This is only because of want of space and not because they are not of importance and interest, and our only regret is we are unable to deal with the report at greater length. The six rupees four annas charged for this report would

be money well spent by any organization or individual in India interested in public health in any of its numerous branches.]

REPORT OF THE TECHNICAL COMMISSION* OF THE HEALTH COMMITTEE

INTRODUCTION

THE Commission is in agreement with the conclusions of the Burnet and Aykroyd Report that deficiencies in important nutrients are a common feature of modern diets and that these deficiencies usually occur in the protective foods (foods rich in minerals and vitamins) rather than in the energy-giving foods (proteins, fats and carbohydrates). The Commission has set out its findings in two parts: part I dealing with the requirements of energy-giving foods; part II with mineral and vitamin requirements.

PART I

Energy, protein and fat requirements

1. *Calorie requirements.*

(a) An adult, male or female, living an ordinary everyday life in a temperate climate and not engaged in manual work is taken as the basis on which the needs of other age-groups are reckoned. An allowance of 2,400 calories net per day is considered adequate to meet the requirements of such an individual.

(b) The following supplements for muscular activity should be added to the basic requirements in (a):

Light work:	up to	50	calories per hour of work.
Moderate work:	"	50-100	" "
Hard work:	"	100-200	" "
Very hard work:	"	200	" and upwards per hour of work.

* The personnel of the Commission was as follows:—

United Kingdom.

Professor E. P. Cathcart, Professor of Physiology, Glasgow University;
Professor E. Mellanby, Secretary-General of the Medical Research Council, Professor of Physiology at the Royal Institution, London;
Sir John Boyd Orr, Director of the Imperial Bureau of Animal Nutrition, Reid Library, Rowett Institute, Aberdeen.

United States of America.

Professor E. V. McCollum, Professor of Biochemistry, Johns Hopkins University, Baltimore;
Dr. Mary Swartz Rose, Columbia University, New York;
Dr. W. Sebrell, Chief of the Department of Nutrition, National Institute of Hygiene, Washington, D.C.

France.

M. J. Alquier, Secrétaire général de l'Institut scientifique d'hygiène alimentaire, Directeur de l'Institut national agronomique, Paris;
Professor L. Lapicque, Professor of Physiology at the University of Paris, Faculté des sciences, Sorbonne, Paris.

Scandinavian States.

Professor Axel Höjer, Generaldirektor, Medicinalstyrelsen, Stockholm;
Professor C. Schiøtz, Professor of Hygiene at the University of Oslo.

U. S. S. R.

Professor B. Sbarsky, Director of the Central Nutrition Institute, Moscow.

(c) The energy requirements for other ages and for mothers can be obtained from the following table of coefficients:

Age (years)	Coefficient	Calories
1-2	0.3	720
2-3	0.4	960
3-5	0.5	1,200
5-7	0.6	1,440
7-9	0.7	1,680
9-11	0.8	1,920
11-12	0.9	2,160
12 and upwards (male and female).	1.0	2,400
Women:		
Pregnant	1.0	2,400
Nursing	1.25	3,000

The requirements for babies under 1 year are difficult to specify except in terms of body-weight, but the following allowances are considered adequate:

Age (months)	Grammes per kilogramme of body-weight
0-3	100
3-6	90
6-12	80-90

The muscular activities characteristic of every healthy child and adolescent necessitate additions to the basic requirements shown in (c). It is suggested that the activities of children of both sexes from 7-11 years be considered as equivalent to light work, of boys from 11-15 years as moderate work and of girls from 11-15 upwards as light work.

Allowance must also be made for women engaged in household duties, whether pregnant or not; these have to be reckoned as equivalent to light work for eight hours daily.

2. Protein requirements.

In practice, the protein intake for all adults should not fall below 1 gramme of protein per kilogramme of body-weight. The protein should be derived from a variety of sources, and it is desirable that a part of the protein should be of animal origin.

During growth, pregnancy and lactation, some animal protein is essential, and in the growing period it should form a large proportion of the total protein.

The following allowances of total protein are recommended:

Age (years)	Calories per kilogramme of body-weight
1-3	3.5
3-5	3.0
5-15	2.5
15-17	2.0
17-21	1.5
21 and upwards	1.0
Women:	
Pregnant	2.0
Nursing	2.0

3. All the above figures on which the Commission has agreed are average values and it is essential that they should be interpreted in the light of this fact.

4. Fat requirements.

Fat must be a constituent of the normal diet, but the data at present available do not suffice to permit a precise statement of the quantity required.

5. The influence of climate on dietary requirements.

In cold climates, the energy-content of the diet should be increased.

PART II

Mineral and vitamin requirements

6. The Commission recognizes the fact that the deficiencies of modern diets are usually in the protective foods (foods rich in minerals and vitamins) rather than in more strictly energy-bearing foods (rich in

calories). Among the former are, first and most important, milk and milk products, eggs and glandular tissues; then green-leaf vegetables, fruit, fat, fish and meat (muscle). Among the energy-bearing foods of little or no protective power are sugar, milled cereals and certain fats.

Of energy-giving foods, unmilled cereals are not rich in protective nutrients and the more they are refined the less is their protective power. Many fats, especially when refined, possess little or no protective constituents. Refined sugar is of value only as a source of energy; it is entirely devoid of minerals and vitamins. The increasing habit of the large sugar consumption tends to lessen the amount of protective foods in the diet and is to be regarded with concern.

7. Requirements of pregnancy and lactation.

The Commission has attempted to define the quantitative needs of protective foods for perfect nutrition in terms of the requirements for the pregnant and nursing woman. She should be regarded as the member of the population needing the greatest 'protection' in order to ensure adequate physical endowment for the child at birth and optimum nutrition during infancy.

The greatest difficulty in arranging such a diet is to provide adequate calcium, phosphorus, iron and vitamins B₁, B₂, C and D.

8. Milk, whole or skimmed, is a rich source of calcium salts and phosphates and of vitamin B₂, also a good source of vitamin B₁; milk fat is an excellent source of vitamin A. Eggs contain vitamins A, B₁, B₂ and D and are rich in iron. The proteins of these foods are not only themselves of the highest nutritive value, but also improve the utilization of the protein contained in cereals and vegetables. Milk has an additional advantage in the abundance and availability of its calcium salts and phosphates; these enhance the effect of any vitamin D derived from other articles of diet or from sunshine. Milk, although itself poor in iron, renders more effective the iron contained in the diet.

9. Ordinary diets are usually inadequate in vitamin D and, except in sunny seasons and sunny countries, a small daily ration of cod-liver oil is to be recommended in the diet of the pregnant and nursing mother and in that of the growing child. Fish-liver oils are the richest known natural sources of vitamin A and are also important sources of iodine. In goitrous regions, where sea-fish are not available, the provision of extra iodine in the form of iodized salt or in some other way is recommended.

10. An extended dietary use of the potato is recommended to replace part of the sugar and highly milled cereals in the ordinary diet. Potatoes provide extra vitamin C and more readily available calcium and phosphorus than are present in cereals. Potatoes also yield more iron and B vitamins than milled cereals.

The above paragraph applies to countries where potatoes are abundant, but it is of general application, due account being taken of local resources.

11. Requirements of other adults and children.

Tables I, II, III and IV contain details of specimen diets derived from investigations made in Great Britain, the United States and Scandinavian countries, considered satisfactory for a pregnant or nursing woman and for infants and children of ages up to 5 years. They are put forward as models which could be modified in many particulars according to national dietary habits and supplies, provided that the dietary principles contained in them are duly regarded.

The protective foods in table I are arranged to yield approximately 1,400 calories without inclusion of cereals, fats or sugar; these can be added as required to satisfy the energy requirements of any individual. For adults other than the pregnant and nursing woman, the amount of protective foods might be reduced, if necessary, for economic reasons. For growing children, however, the maintenance of a high proportion of protective foods should be the aim.

In tables II, III and IV, specimen diets are drawn up on the above basis for age-groups 0-1, 1-2, 2-3 and 3-5 years. Since the rate of growth of a child decreases with advancing age, approximately the same amount of the protective foods will suffice for 10-15-year-old children as is required for the 5-year-old child.

12. General recommendations.

A. Although a simplified diet may be so constituted from a few protective foods as to be satisfactory, it is a general principle that variety in diet tends to safety, provided it contains a sufficiency of the protective types of food materials.

B. White flour in the process of milling is deprived of important nutritive elements. Its use should be decreased and partial substitution by lightly milled cereals and especially by potatoes is recommended. The consumption of an excessive amount of sugar is to be condemned, and in this case also partial replacement by potatoes is urged.

C. Milk should form a conspicuous element of the diet at all ages. The Commission commends the tendency manifested in some countries to increase the daily intake up to one litre per day for pregnant and nursing women, as well as to provide an abundant supply for infants, children of all ages and adolescents. The practice of providing milk either free or at a reduced price to these is highly recommended.

The Commission desires to draw attention to the high nutritive value of skimmed and separated milk, which, although deprived of its vitamin A through removal of the fat, retains the protein, the B and C vitamins, the calcium and other mineral elements. The Commission deplores the large wastage in many countries of this valuable food.

D. Fresh vegetables and/or fruit should always be constituents of the normal mixed diet. Adequate provision of the vitamins other than vitamin D can be readily accomplished by inclusion in the diet of optimum amounts of protective foods. Where these are not available, only such vitamin preparations as are officially controlled and approved should be permitted.

E. The Commission emphasizes the need for provision of extra vitamin D, either as cod-liver oil or as irradiated products, wherever and whenever sunshine is not abundant, especially in the period of growth and during pregnancy.

13. Problems recommended for further study.

A. Assessment of the nutritional state of children.
B. Nutritive food requirements during the first year of life.

C. Minimum vitamin and mineral requirements.

D. Minimum fat requirements.

E. The nutritive and 'supplementary' values of the different protein-containing foods, to determine to what extent and in what forms animal protein is necessary for growth and health.

F. The relative nutritive value of different cereals according to the degree of milling.

G. The extent to which the increasing consumption of sugar is detrimental to health.

H. Influence of climate on food requirements.

I. The extent to which diets in common use fall below the standards recommended in this report.

TABLE II

Infants

Age 0-1

Breast-feeding is strongly recommended during the first nine months of life. Where and when sunshine is not abundant, each breast-fed infant should receive a small daily ration of cod-liver oil, up to 6 grammes daily, to supply the antirachitic vitamin D. This is even more important for artificially-fed infants. Fresh fruit and/or vegetable juice to provide antiscorbutic vitamin C should also be given to every infant, especially the artificially-fed.

When breast-feeding is not possible, the basis of the infant's diet should be milk, suitably modified if

TABLE II—concl'd.

necessary, and supplemented by an adequate amount of substances rich in vitamins A, C and D.

Where complete breast-feeding is impracticable, partial breast-feeding is urged, and the supplementary diet should consist of cow's milk and other suitable protective foods.

Age 1-2 (1,000 calories)			
Food	Amount (grammes)	Calories	Protein (grammes)
A. Protective foods			
Milk	1,000	660	32
1 Egg (or equivalent, as 30 grammes meat or fish or liver, if available) ..	48	70	6
Green leafy vegetables	30-60	15	—
Potato (and other root vegetables) ..	50	50	1
Cod-liver oil ..	3	30	—
A source of vitamin C (raw vegetable or fruit)			
		825	39
B. Supplementary energy-yielding foods			
Fats (butter, if possible)	3.5	25	—
Cereals (as wheat) ..	50	150	7
TOTAL ..		1,000	46

TABLE III

Age 2-3 (1,200 to 1,300 calories)

Food	Amount (grammes)	Calories	Protein (grammes)
A. Protective foods			
Milk	1,000	660	32
1 Egg (or equivalent, as 30 grammes meat or fish or liver, if available) ..	48	70	6
Green leafy vegetables	60-100	20	2
Potato (and other root vegetables)	100	100	2
Cod-liver oil ..	3	30	—
A source of vitamin C (raw vegetable and fruit)			
		880	42

ANNUAL REPORT OF THE INSTITUTE FOR MEDICAL RESEARCH, FEDERATED MALAY STATES, FOR THE YEAR 1934

During the year under review the institute has been handicapped by a further decrease in the funds available for expenditure. Year by year successive decreases in the grants have, of necessity, been imposed, until, to-day, the estimates for annually recurrent expenditure are below sixty per cent of the corresponding total for 1930. The staff has throughout co-operated most loyally in effecting all possible economies, but the policy of patching and repair cannot be continued indefinitely; no further reductions are possible under the present conditions, and some increase in expenditure will be necessary in future years. A serious feature has been the reduction in the allocation for the library.

Investigations have further confirmed the great similarity, if not the identity, of the viruses of 'rural' tropical typhus ('K' type) and of Japanese river fever. Experiments have also been undertaken, on the insect carriage of the local typhus-like fevers, that have demonstrated beyond doubt the capacity of the rat flea *X. cheopis* to function as a vector of 'urban' typhus ('W' type) from rat to rat, and hence, in every probability, from rat to man. On the other hand, *X. cheopis* failed to 'carry' the virus of 'rural' typhus and, moreover, experiments with *D. andersoni* (a vector of Rocky Mountain spotted fever) and with *R. san-guineus* were also attended by negative results.

Atebrin has received further attention: comparing in detail the efficacy of courses of this drug *vis-à-vis* that of short curative courses of quinine in estate lines practice. Under the experimental conditions little is to be gained clinically from the employment of the more expensive preparation while from the economic point of view of estate management the scales are definitely in favour of quinine. On one of the estates, where these experiments were carried out, *A. maculatus*, *A. umbrosus* and *A. separatus* were all found to be infected—the last species is now recorded as a local carrier for the first time.

The chemical division has examined the usual large number of routine specimens that year by year are submitted for report. Little time has been available for special problems, but the mineral constituents of the raw waters of local supplies by the spectrographic method and the depression of the freezing point of local milks by means of the Hortvet cryoscope have been investigated: the majority of the determinations have been made on samples taken under supervision from cows of various breeds and from buffaloes.

[This brief abstract is taken from the general remarks of the Director, but in the research section of the report the pages devoted to tropical typhus and malaria are of special interest and should be read in the original by those interested as they are fairly long and do not readily lend themselves to abstraction, but these two sections by no means exhaust all the research activities carried on at the institute, as investigations into organisms of the enteric group, typing of pneumococci, experiments with vaccine lymph, and testing of water supplies are also reported among other lines of inquiry being engaged in. There is also the immense amount of routine bacteriological, pathological and public health laboratory work recorded which indicates this laboratory is one of the busiest in the East.]

A REPORT OF THE SIXTY-FIRST YEAR'S WORK IN INDIA OF THE MISSION TO LEPERS

A Review of the Year's Medical Work

In looking over the statistics for the past few years, the most striking feature is the rapid increase in out-patients treated. Within the last two years the number has more than doubled itself, and now exceeds the total of the inpatients under treatment. This is a very important extension of the work of the mission.

On the other hand, the results from outpatient treatment are apparently not as satisfactory as those

obtained among the inmates; the disease being arrested in only 1.3 per cent of the former, as compared to 14.7 in the latter. While outpatient treatment is useful, the impossibility of regular attendance and the difficulty of backing up drug treatment with the far more important dietary and hygienic measures, detracts considerably from its value.

Many of those who attend the outpatient clinics are would-be inpatients, for whom accommodation is not available. The workers of the mission are everywhere faced with the sad problem of turning away many who need and beg for help, but for whom there is no room.

It is estimated that there are, about one million people suffering from leprosy in India, of whom probably at least 200,000 are highly infectious, and are spreading the infection to the next generation. How can the mission break this vicious circle, with its accommodation for only six or seven thousand?

Perhaps the answer may come to a certain extent through the 842 'arrested without deformity' during the last year. This is the brightest feature in the statistics—842, an ever-increasing number compared with 570 in 1932 and 710 in 1933. If these could be trained in the technique of isolation, and act as missionaries when they return to their village, they might teach their fellow-villagers the danger of the infectious leper to the community, especially to the children.

Leprosy is so easy to prevent—so difficult to cure, and prevention can only be carried out in India when the villager recognizes the danger and understands the simple measures necessary for carrying it out.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE (UNIVERSITY OF LONDON) INCORPORATING THE ROSS INSTITUTE. REPORT ON THE WORK OF THE SCHOOL FOR THE YEAR ENDED 31ST JULY, 1935

This report includes an account of the operations of the Ross Institute of Tropical Hygiene during the first complete year since its incorporation in the School.

Close relations have been maintained with the Ministry of Health and the Medical Research Council and we are grateful to both these bodies for assistance in carrying out much of our research work.

Full advantage has been taken during the past year of the policy of the board of management to encourage members of the staff to pay visits to tropical and sub-tropical countries for the purpose of conducting special investigations or studying local problems.

Division of clinical tropical medicine.—As stated in last year's report, Sir John Megaw was appointed to lecture on leprosy, dengue, sandfly fever and typhus fevers, and Colonel F. P. Mackie on cholera and plague. These lectures have been given this year and the students have appreciated them very much.

The subjects under special investigation during this period have included: (1) sprue; (2) malarial anaemia in man and experimental haemoglobinuria in monkeys; (3) blackwater fever; (4) the immunological reactions in helminthic diseases. The lines followed have already been indicated in previous reports.

Department of helminthology.—A notable gift has been made to the department by the council of the Royal College of Surgeons. The collection of miscellaneous specimens and microscopical preparations which had been handed to the College by the late Professor Cobbold's executors and had been stored in the Hunterian Museum for many years has been transferred to the department of helminthology. Among the specimens were found a number of early preparations made by Sir Patrick Manson in China and these have been placed in the school museum.

Department of entomology.—It has recently been shown that the parasite of bird malaria has a harmful effect upon the mosquito vector. It appears desirable that similar studies should be made on several species of *Anopheles* with one of the human malaria parasites. Dr. Wigglesworth's published work has shown that

metamorphosis is controlled by a hormone: he suggests that the phenomenon of diapause may have a similar explanation. This is of considerable interest, because diapause has puzzled entomologists for many years: owing to these interruptions of development, fluctuations in the numbers of insects of economic importance are much more complex and much more difficult to control than they would otherwise be.

Department of protozoology.—The amount of time allocated for the teaching of hæmatology and protozoology is extremely limited and in consequence it has been found necessary to restrict the scope of instruction to such investigations as are essential to clinicians in the diagnosis of disease. The close co-operation with the school of the hospital staffs at Gordon Street and Albert Dock Hospitals has been invaluable in that a supply of fresh material has been made available for practical laboratory studies. The various pathogenic parasites of man, the trypanosomes, leishmanias, spirochaetes, amœbæ and flagellates are all kept in culture and thus the students are able to study these in the living state. Further, Sir Rickard Christophers has very kindly demonstrated the malarial parasites in freshly dissected mosquitoes and the students have had ample opportunity of seeing the technique of examining infected mosquitoes for oöcysts and sporozoites. Colonel James of the Ministry of Health and Mr. Shute have supplied numerous fresh films of the various parasites of malaria and the department is much indebted to them. Old students of the school have, during the past year, provided an abundance of material for laboratory work, and in this connection special thanks are due to the medical men in Assam and in India who are working in collaboration with the Ross Institute.

Dr. B. M. Das Gupta from the Calcutta School of Tropical Medicine has been working in the department from the beginning of June while holding a Rockefeller travelling scholarship.

Division of bacteriology.—The teaching work of the division has not differed from that of previous years. Professor Wilson's investigation into the bacteriological grading of milk is now completed. Professor Wilson has completed his report, and this has been accepted by the Medical Research Council for publication in their special report series. The main conclusions are that neither of the present methods, i.e., the plate count or the coliform count, is suitable as a routine test for the grading of milk. On the other hand, a modified methylene-blue reduction test has been devised, which is simple, inexpensive, and accompanied by only a small experimental error. It is hoped that this test will be used widely in the control of milk supplies in the country.

Miss Wills, working with a Lady Tata Memorial Scholarship, and assisted by Mrs. Stewart, has continued her study of macrocytic anæmia. The response of the *rhesus* monkey to various anæmia-producing stimuli showed that these animals were suitable subjects for experiment. By feeding them with a deficient diet, a macrocytic anæmia similar to tropical macrocytic anæmia of man was produced. Animals thus rendered anæmic were used for an investigation, in collaboration with the biochemical department, of the nature of the hæmopoietic factor present in marmite with particular reference to the newly-described vitamin B₁₂ fractions.

Division of biochemistry and chemistry.—The main work of the division is of a research nature and has been continued on two main lines, (a) on the biochemistry of the lower fungi, and (b) in collaborative work with certain members of the staff of the division of bacteriology and immunology on problems connected with immunological chemistry.

Division of public health.—Much of the work of the Dean's office falls inevitably upon the staff of the division and a great deal of time is spent on meeting the requirements of students and of scientific visitors from overseas who make this school their headquarters during their stay in this country.

Mr. Clay left for India towards the end of the summer term where, in company with Dr. Ramsay of the Ross Institute, he paid a large number of visits to factories and estates in order to study and, where necessary, to advise on systems of sanitation.

Ross Institute of Tropical Hygiene.—The activities of the Ross Institute of Tropical Hygiene may be classed generally as:—

1. Work overseas consisting of:—
 - (a) Practical assistance to governments and industrial undertakings;
 - (b) Scientific research in association with this practical work.
2. Work in London consisting of:—
 - (a) Assistance and advice chiefly to commercial companies; and
 - (b) The teaching of tropical hygiene to both medical men and laymen who have been or who are going abroad.

Malaria research unit.—The malaria research unit under the direction of Professor Sir Rickard Christophers has continued to function as a centre for experimental work on malaria and to carry out researches and other activities in connection with this important disease.

The main research during the year has continued to be that directed to determining the biochemical principles underlying the action of antimalarial drugs. As the absorption of quinine by such material as isolated parasite substance and red cells has been found to be that characteristic of a base absorbed by protein, the absorption of acid and base under such circumstances has been studied in some detail. The results obtained have justified the time spent as they have indicated very definitely the mechanisms and equilibria involved so that it will be possible as a result to investigate absorption of quinine and other drugs from a more informed point of view. The results of this work which are on the point of publication indicate that absorption under such circumstances is to be regarded as combination between the protein of the organism or cell and the acidic or basic element forming what are virtually 'protein salts', there being always a fraction unabsorbed represented by the 'hydrolysis' of these salts under the particular conditions of the experiments. Where the acid or base is very weak as is the case with chemotherapeutic substances the fraction unabsorbed becomes very great. The significance of these observations lies in the fact that quinine and all other known antimalarial drugs have a basic side chain the importance of which can scarcely be accidental. The absorption of the substances, it is thought, must be governed in the first place by this fact, thus bringing quantitative considerations into play similar to those found in the absorption of acid and base by protein.

Tropical mycology.—Further researches have been made during the past year on the biological reactions in a large number of fungi and bacteria in media containing various carbohydrates and allied substances. A new reaction which may be used in the future classification of organisms has been investigated.

Institute of Agricultural Parasitology.—The researches carried out by the staff of the Institute at Winches Farm have, as in former years, been concerned with the helminth diseases of (a) farm stock, (b) poultry and game, (c) economic plants and (d) insect pests.

THIRTY-SIXTH ANNUAL REPORT OF THE INCORPORATED LIVERPOOL SCHOOL OF TROPICAL MEDICINE, 1934-35

Department of tropical medicine.—The professor and his colleagues have continued their researches in chemotherapy during the year and have devoted their attention particularly towards investigating the fate of different types of arsenical compounds after introduction into the animal body.

They have also continued to examine the therapeutic action of new compounds submitted to them by the

Chemotherapy Committee of the Medical Research Council.

Department of tropical hygiene.—The autumn term of 1934 was devoted to organizing the new department, there being no course of instruction for the Diploma in Tropical Hygiene during this period.

During the Lent Term, 1935, in addition to the usual course of instruction for holders of the Diploma in Tropical Medicine, a special short course in tropical hygiene was also held for non-medical persons proceeding to posts of various kinds in the tropics.

The School and University have granted leave of absence to Professor Blacklock to go to the East for a period extending from 13th July to the end of the year in order to make a comparative study of the methods of applied hygiene, especially rural hygiene, which have proved most useful. His itinerary includes visits to China, Netherlands East Indies, Malaya, India and Ceylon.

Department of entomology.—Professor Patton has continued his comparative studies of the male and female terminalia of the higher flies. The results of these studies have been most encouraging, as they are already throwing new light on the true relationships of the main divisions to each other, and, incidentally, go a long way to simplifying the classification of these flies. A series of papers dealing with these characters in several subfamilies, some of which include species of medical and veterinary importance, have been published. In connection with this work, a large amount of material from many parts of the world has been identified.

Department of parasitology.—During the year, extensive rearrangement and classification of the helminthological and protozoological material was

carried out; numerous specimens were identified and added to the departmental collections.

Research into the life-history of certain important parasites of domestic stock has been carried out at Knowsley as opportunity allowed. A considerable amount of important information has been collected.

SIR ALFRED LEWIS JONES LABORATORY, FREETOWN

The work on schistosomiasis, which had occupied much of the time available for research during the past two and a half years, was finally published in October 1934.

In December 1934, a serious outbreak of yellow fever occurred in the Gambia, and at the request of the Colonial Office Dr. T. H. Davey, from the staff of the laboratory, accompanied by Dr. Findlay (of the Wellcome Research Bureau), spent two months in the Gambia immunizing the susceptible population and carrying out various investigations.

In view of the outbreak of yellow fever in the Gambia and the occurrence of a single European case in Sierra Leone, the Director of Medical and Sanitary Services asked the laboratory to help his department by preparing a pamphlet on the subject of yellow fever and its prophylaxis.

Museum.—Work in the museum during the year consisted chiefly in adding further panels illustrative of various tropical diseases. The majority of such gifts have now been dealt with in a fairly adequate manner.

The preventive aspect of tropical medicine has not as yet been adequately shown, owing chiefly to shortage of illustrative material; it is hoped that the Curator during her tour in the East will be able to obtain photographs and specimens which will aid in the making up of this deficiency.

THE TREATMENT OF LOBAR PNEUMONIA WITH INTRAVENOUS INJECTIONS OF ALCOHOL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I was interested in the article which appeared in your paper for December 1935. In this connection I would like to point out a few contra-indications which were mentioned in *Le Journal de Medecine de Lucas-Championniere*, which gives the following abstracts on the thesis of M. Michel Hetroy on indications and contra-indications for intravenous alcohol, viz:

'INDICATIONS FOR INTRAVENOUS ALCOHOL

(1) *Acute and chronic lung diseases.*—True acute pneumonia (indication for alcoholic treatment is rare in view of the usual favourable course of the disease); pneumonia of old people or as a result of injuries ending in sepsis (prognosis often hopeless); lung abscess (useful as an adjunct, but its use does not exclude surgical interference which remains the only effective treatment); influenzal broncho-pneumonias (good effect); following shock and post-operative pulmonary complications (brilliant and rapid results).

(2) *Septicæmias.*—Puerperal and all other types of septicæmias.

(3) *Acute barbituric intoxications.*—It will be seen from the above that the indications for intravenous alcohol are varied and, as Hetroy has remarked, they can be further extended. It is evident that they can be employed with success in all cases where alcohol by mouth is indicated and where its oral use is contra-indicated (operations on the stomach). For example, it may be used in debilitating types of influenza and

fractures of the thigh, in old people to combat hypostatic congestion (the author has had several cases of this type), in all infections where pulmonary complications are feared, in cardiac cases with chronic venous congestion and, finally, in all cases where infection is present or imminent.

Contra-indications.—The chief one is when the method is withheld too late. In advanced liver, kidney or heart diseases, alcohol should be used cautiously and in small doses. The same applies to hæmoptyses, although, according to the author, these are not contra-indications. It has been said also that intravenous alcohol should not be used in infants, but if small doses such as 0.5 c.cm. per kilo are given intramuscularly, no danger is to be anticipated'.—Yours, etc.,

JOHN S. BRADFORD, M.D.,
Group Medical Officer.

BINNAGURI P. O.,
DOOARS.

Service Notes

APPOINTMENTS AND TRANSFERS

MAJOR-GENERAL A. W. F. HARVEY, K.H.S., is appointed to be Deputy Director of Medical Service, Northern Command, *vice* Major-General T. G. F. Paterson, C.B., D.S.O., K.H.P., retired. Dated 24th November, 1935.

Colonel E. W. C. Bradfield, C.I.E., O.B.E., V.H.S., is appointed Honorary Physician to the King, 14th August, 1935, *vice* Major-General H. R. Nutt, retired.

Lieutenant-Colonel A. A. C. McNeill is appointed Honorary Physician to the King, and is promoted Brevet-Colonel 6th August, 1935, *vice* Colonel H. E. Stanger Leathes, retired.

Lieutenant-Colonel G. G. Jolly, C.I.E., V.H.S., Deputy Director-General, Indian Medical Service, is appointed to officiate as Public Health Commissioner with the Government of India, in addition to his own duties, from the 8th September, 1935, till the 26th November, 1935, and as whole-time Public Health Commissioner with effect from the 27th November, 1935 (forenoon), *vice* Brevet-Colonel A. J. H. Russell, C.B.E., K.H.S., granted leave.

Lieutenant-Colonel Dewan Hakumat Rai, M.C., is appointed to officiate as Deputy Director-General, Indian Medical Service, with effect from the 27th November, 1935 (forenoon), *vice* Lieutenant-Colonel G. G. Jolly, C.I.E., V.H.S., appointed to officiate as Public Health Commissioner with the Government of India.

Major G. Verghese, Superintendent, Bihar and Orissa Jail Department, is confirmed in that appointment.

The services of Captain A. N. Chopra are placed temporarily at the disposal of the Government of Bombay, with effect from the afternoon of the 8th November, 1935.

Captain C. K. Lakshmanan is appointed temporarily as a supernumerary officer in the Port Health Department, Bombay, with effect from the forenoon of the 16th December, 1935.

Captain B. S. Sandhu made over charge of the Presidency Jail to Lieutenant-Colonel M. A. Singh, on the forenoon of the 6th January, 1936.

The services of Captain B. S. Sandhu, formerly Superintendent, Presidency Jail, are replaced at the disposal of the Government of India on the expiry of the leave granted to him.

The services of Major J. R. Katariya, formerly Superintendent, Presidency Jail, are replaced at the disposal of the Government of India, Army Department, for military duty, with effect from the 16th September, 1935.

This cancels previous notifications.

Captain B. N. Hajra did general duty at the Medical College Hospitals, Calcutta, for the period from the 25th December, 1935, to the 1st January, 1936. He is appointed as Civil Surgeon of Bakarganj, *vice* Dr. Charu Chandra Sinha.

Captain C. K. Lakshmanan is appointed provisionally as Port Health Officer, Calcutta, with effect from the 10th February, 1936, until further orders.

To be Captains (on probation)

1st November, 1935

Abraham Henry Barzilay, with seniority as Lieutenant 1st November, 1930, and as Captain 1st November, 1933.

Robert Keith Muir, C.M., with seniority as Lieutenant 6th August, 1931, and as Captain 1st May, 1934.

Patrick Michael McSwiney, with seniority as Lieutenant 5th September, 1932, and as Captain 1st May, 1934.

To be Lieutenants (on probation)

1st November, 1935

John Andrew Lawson McCullough, with seniority 1st November, 1934.

Daniel John Percy Parker, with seniority 1st November, 1934.

Clifford Llweellyn Ash, with seniority 1st November, 1934.

Thomas Cecil McGarrie McDougall Morrison, with seniority 1st November, 1934.

Victor Douglas Gordon.

Brian de Burca.

Donald Ross Nicol.

Joseph Morgan.

Thomas Sommerville.

Lieutenant C. K. Byrnes and Lieutenant G. F. Adye Curran are reinstated to the establishment, 1st November, 1935.

PROMOTIONS

Majors to be Lieutenant-Colonels

C. M. Nicol. Dated 14th November, 1935.

D. R. Thomas, O.B.E. Dated 30th November, 1935.

P. Verdon. Dated 1st December, 1935.

D. V. O'Malley, O.B.E. Dated 8th December, 1935.

S. A. Phatak. Dated the 23rd December, 1935.

Lieutenants (on probation) to be Captains (on probation)

J. Duffy. Dated 15th October, 1935, with seniority 23rd April, 1933.

K. Cunningham. Dated 15th October, 1935, with seniority 23rd April, 1933.

I. J. Franklen-Evans. Dated 15th October, 1935, with seniority 23rd April, 1933.

LEAVE

Lieutenant-Colonel C. H. Smith, O.B.E., an Agency Surgeon, is granted leave on average pay for 8 months combined with leave on half average pay for 1 year and 8 months, with effect from the forenoon of the 21st November, 1935, pending retirement.

Major H. H. Elliot, M.B.E., an Agency Surgeon, is granted leave on average pay for 3 months combined with study leave for 3 months and leave on half average pay for 3 months, with effect from the afternoon of the 15th October, 1935.

In supersession of previous notification, Captain A. M. Sheridan, Civil Surgeon, Coorg, was granted leave on average pay for 6 months combined with study leave for 6 months, with effect from the 4th September, 1935.

Captain B. S. Sandhu, lately Superintendent, Presidency Jail, is allowed leave on average pay for 2 months, with effect from the 6th January, 1936.

RETIREMENTS

Major-General T. G. F. Paterson, C.B., D.S.O., K.H.P., retires. Dated 24th November, 1935.

Colonel E. C. Hodgson, D.S.O., K.H.P., retires. Dated 22nd October, 1935.

Lieutenant-Colonel B. Higham, C.I.E. Dated 14th December, 1935.

Notes

ULTRA-VIOLET RADIATION

THE value of ultra-violet radiation is appreciated far less in this country than in many countries in the West. This is partly because anything that is abundant is never valued at its full worth—and ultra-violet rays are abundant in India for most of the year. Despite the fact that a large percentage of the population live on a diet inadequate in most vitamins, the diseases caused by vitamin-D deficiency are comparatively rare except in the towns where the smoky atmosphere prevents these rays reaching the earth, and those who live on it.

The sun's rays, valuable as they are in therapeutics, have their limitations—they contain rays other than ultra-violet rays that may be harmful in any particular case, the dosage—especially in towns—is difficult to estimate and therefore difficult to control, and the sun's rays are difficult to localize. For these reasons artificial ultra-violet radiation is often to be preferred.

The Hanovia Company, one of the largest manufacturers of equipment for light therapy, have issued a very interesting little booklet entitled *The Most Vitalizing of all Measures*. In this they quote one hundred clinical references to the use of actinotherapy in general practice. The following extracts which may prove of interest to our readers are given:—

'The resistance of some patients may be so depressed that they are unable to eradicate the trouble in spite of

surgical help; in these cases the greatest attention must be paid to diet and care of the bowels, iron and vitamin therapy are necessary, and the most vitalizing of all measures, general ultra-violet light therapy, is given daily'.

'Light is of universal necessity to the life and well-being of cell development and sustenance. Without light, proper metabolism is impossible, and when scientifically applied to suitably selected cases, it will do infinitely more than any other agent in the service of man to restore normal physiological conditions'.

Anæmia.—The majority of the cases treated were either children who were anæmic, particularly the type following upon the occurrence of an infectious disease or other debilitating illness, or children suffering from debility, a vague term signifying rather a tendency to disease than any actual disease, but characterized by such symptoms as fitful appetite, poor sleep, nervousness or malnutrition. After a course of ray treatment such a case usually goes on improving without further treatment'.

Acidosis and gastric ulcers.—'Ultra-violet light often relieves hyperacidity in certain miscellaneous disorders involving the secretory function of the stomach, and it is probable that the mechanism involved in this reaction plays an important part in effecting symptomatic relief in gastric ulcer. Certain it is that the pain of a gastric ulcer will sometimes clear up as quickly and as effectually as when a hypodermic injection of morphine has been given. Of course, there are other factors at work besides the lowering of the acid content. With the erythema produced, there is an increase in the elimination of toxins, and even their production is lessened by the destruction of the bacteria producing them'.

Colitis.—'From an intimate study of almost 3,000 cases of all types of colitis, I am convinced that a large number are associated with, if not due to, endocrine disturbances. The basic treatment is ultra-violet radiation, and to this is added infra-red radiation. When colitis is due to vitamin deficiency good results may be expected. Another established fact is that in some way or other ultra-violet radiation activates the deficient endocrine glands and thus tends to stabilize the endocrine system in which co-ordination has been disturbed. To one who has used ultra-violet extensively, examples are countless of increased weight, the disappearance of weakness, the building up of resistance against infection, relief of insomnia, improvement of appetite, most of which is without doubt due to its action on some part of the endocrine system and hence applicable to all forms of colitis of neurogenic origin and extremely useful in that almost hopeless of all colitides—the tuberculous type. The abdominal surface is first exposed for one half-hour to the infra-red lamp. This is followed by increasing dosage front and back with ultra-violet radiation, using the mercury vapour lamp'.

Eczema.—'Those of us who specialize in light therapy.....treat many cases of chronic eczema of all types which have defied the efforts not only of the general practitioner, but also of the skin specialist. I have just completed, with success, the treatment of a patient who had suffered from chronic eczema intermittently for thirty years'.

'The most dramatic cures were obtained in cases of eczema. In some cases chronic and unyielding to other forms of treatment for years, they yielded under treatment by artificial sunlight'.

Psoriasis.—'In spite of the cynic who stated that any new method will cure psoriasis—at first, there is no doubt that the mercury vapour lamp has proved itself a most astonishing success. Long-standing cases require more treatments than those of recent origin, but I have yet to meet with a case that is not greatly benefited by the treatment'.

'Psoriasis varies so greatly in type and distribution that it is obvious that the technique cannot be standardized. Provided the technique is adapted to each patient, many of the cases hitherto regarded as

'failures will respond well to treatment with ultra-violet radiation'.

Lumbago and sciatica.—Quick and lasting relief of a lumbago attack is obtained from regional doses of ultra-violet rays. Dr. J. Lepsky of the Soviet Medical Service says of 1,152 cases:—'The sum total of results obtained by means of local erythema doses justifies us in concluding that irradiation can be considered as a method of choice. Apart from its excellent therapeutic effects, this method possesses still further advantages:—the rapidity of the therapeutic results, the cheapness of this treatment; the decided shortening of the working incapacity period'.

Other forms of nervous pain likewise benefit greatly from ultra-violet radiation, suited to the case; migraine, *tic dolozeux*, and periodic headaches are quoted by Dr. F. Humphris. Dr. F. Talbot uses general light baths to clear up chronic neuralgia after dental surgery.

Pulmonary.—The commentary of Dr. Bach, the physician who introduced general irradiation with the quartz lamp, still holds good:—'It is primarily the organism itself which possesses powers by which healing is effected, and like all other remedies, natural and artificial light baths can only serve to stimulate and assist these natural powers. Where they are capable of improvement, success will be obtained by natural and artificial light baths and climatic cures in the treatment of all forms of tuberculosis superior to those yet achieved by any other method'.

The booklet, which is well worth reading, is available on request from Malgham Brothers, 26, Old Custom House Road, Fort, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters. Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

'MAN-MADE' MALARIA IN INDIA*

By J. A. SINTON, M.D., D.Sc.

LIEUTENANT-COLONEL, I.M.S.

(Director, Malaria Survey of India, Kasauli)
(Indian Research Fund Association)

IN touring through India, the public-health worker and the malariologist cannot fail to be forcibly impressed by the numerous occasions upon which the prevalence of malaria has been determined, or markedly increased, by the activities of man in areas where this disease was previously mild or even unknown.

The inhabitants of India do not appear to be content with the large amount of malarial sickness with which Nature has provided them, but, in many instances, they would seem almost to have made special efforts to increase the disease. Many of such harmful conditions are due to ignorance, but, in other instances, a deliberate neglect of those sanitary and other precautions, which have been emphasized on so many occasions, has been largely responsible. This applies not only to private individuals and communities, but also to industrial concerns and even to Government departments.

Many of these errors, both of omission and commission, react not only upon the health of the people in the areas concerned, but may affect seriously the economic prosperity and the financial status of the population, and, apart from a loss of revenue to the Governments, administrations and departments concerned, may also require a large expenditure of money to remedy them at a later date.

The effects of human activities in increasing the prevalence of malaria may be divided roughly, for the purposes of discussion, into the following headings:—

(A) Measures resulting in an increase of the malaria-carrying mosquito (*Anopheles*);

(B) The introduction of human malaria carriers; and

(C) Conditions leading to economic stress and a lowered resistance of the population.

These factors are usually seen in combination, and together may produce, and have produced, not only a high morbidity and mortality, but have led in India to industrial and agricultural decay, to economic stress, to the abandonment or inhibition of potentially promising enterprises, and to the depopulation, or the retarded development, of important and potentially rich tracts of country.

* This is the note, slightly amplified, which was circulated to the members of the Malaria Advisory Committee of the 13th All-India Conference of Medical Research Workers at their meeting in Calcutta on 3rd December, 1935.

(A) Measures resulting in an increase of malaria-carrying mosquitoes

Man by his activities has done very much to increase the breeding, multiplication and spread of the dangerous mosquitoes of India. Some of these activities have only produced comparatively local effects, while others have been of a more widespread nature, and so have given rise to more disastrous results.

(a) Local activities

(1) *Domestic*.—Increased facilities for breeding mosquitoes have been provided by:—absence of drainage, or badly constructed, badly planned or badly kept drainage; leaking water taps; water-storage receptacles, cisterns, etc. (Bombay); wells (Bombay, Delhi, Lucknow, etc.); ornamental tanks, fountains, mill-ponds, etc. (Delhi, Bombay, etc.); soak-pits; garden sumps; disused receptacles, tins, etc.; borrow-pits, etc., etc.

General remedies.—Local anti-mosquito measures; education of the public to the dangers of these conditions; appropriate legislation, with penalties (which should be enforced) to ensure the abolition, and prevent the future formation, of such harmful conditions.

(2) *Communal*.—In addition to the conditions already mentioned, communities as a whole may provide increased facilities for breeding dangerous and troublesome mosquitoes through:—absence of proper drainage systems, or the presence of badly planned, badly constructed, or badly controlled ones; improper siting of towns, villages, or buildings; building operations giving rise to borrow-pits, quarries, brick-fields, tanks to soak concrete, etc. (Bombay, Delhi, etc., etc.); badly kept and leaking irrigation channels (Punjab, etc.); over-irrigation (Delhi, etc.); construction of docks, harbours, water-works, etc., without proper sanitary precautions; badly planned and badly controlled water supplies; indiscriminate opening up of jungle in certain areas, etc., etc.

General remedies.—Education of communities and their representatives as to the dangers; legislation to enforce remedial measures and to prevent further transgression; anti-mosquito measures.

(b) Widespread activities

This aspect of the subject is usually connected with engineering works of greater or less extent. While many of the large engineering works in India, such as those connected with the improvement or extension of agriculture and communications, have added to the prosperity of the people in certain areas, in others they have led eventually to a diametrically opposite result. Not only has the economic status of the people been damaged but also their health.

As malarial incidence is intimately bound up with certain species of *Anopheline* mosquito, and as the latter insect can only develop in water, the conditions

in which the latter occurs in any locality are of paramount importance. As pointed out by Bentley and by Stewart, the potentialities of exposed collections of water for breeding large numbers of these insects are very often closely connected with the amount of water edge occurring in relation to the volume of water present. Thus when there is no exposed water edge (*i.e.*, when all exposed water is abolished) there can be no breeding, and, at the other extreme, when the sheet of water becomes so large that the edge in proportion to the exposed surface is infinitesimal, extensive breeding is also inhibited. It is under conditions between these two extremes that the factors are most favourable for the multiplication of such dangerous insects. It is evident, therefore, that, while a decrease of water (drainage, etc., in the Punjab) may be of value in some circumstances, in others this occurrence, due either to artificial (Bengal) or natural (Ceylon, Central Provinces) causes, may be productive of very serious results.

(1) *Increase in breeding places due to increase of water*

(i) Local excavations, etc., by causing exposure of the water table, or by acting as reservoirs of water, either from natural or artificial sources, very frequently give rise to an increased breeding of mosquitoes. Examples of these are borrow-pits (roads, railways, canals, building operations, etc.); brick-fields; wells; badly constructed or badly aligned or badly designed drains, canals, escapes, etc.; poorly graded culverts; disused portions of old canals, or drains; and also many of the conditions mentioned in the previous sections.

(ii) Obstruction to natural drainage often leads to much increase in exposed water. Examples of these are—roads, railways, canals and other embankments cutting across natural drainage channels and without allowance for sufficient waterway (*i.e.*, too few culverts, bridges, etc.) to permit a proper and sufficient run-off of water (universally seen) (*vide* Raja Ram, 1935); hindrance of natural drainage by dams and other obstructions to streams and rivers, resulting in a rise of the subsoil water level in the area above them (Delhi, Sukkur, Ferozepore, etc.).

(iii) An increased influx of water into an area, without the provision of proper drainage, causes increased breeding of mosquitoes. Examples of these are—rice and other wet cultivation (Saharanpore, Mopad, etc.); excessive use of irrigation water in areas where the subsoil water level is already high or likely to be in future (*vide infra* water-logging); ill-kept and leaking irrigation channels; seepages from canals, reservoirs, etc.; badly aligned canals, etc.

(iv) The introduction of large irrigation projects, without the provision of a proper drainage system at the same time, has been productive of much damage mainly through water-logging of the soil. Just as the human system is liable to become oedematous, if there be an obstruction to the veins in carrying away the fluid brought by the arteries, so, in an irrigation system, water-logging occurs if there be not

proper facilities for carrying off the excess water brought into a locality. That this not only results in an increase of malaria, but also in a serious decline in the agricultural prosperity of the area, has been known for many years.

The relationship between water-logging, malaria and agricultural decline was pointed out in India by Baker, Dempster and Yule (1847), about 90 years ago, in connection with the old Western Jumna Canal, and was later emphasized by Taylor (1870). Marchiafava and Bignami (Stedman, 1900), in speaking of the history of irrigation in California, say that this 'has made it plain that if irrigation works are not to become producers of malaria, drainage must proceed *pari passu* with irrigation; when this is not done, the water which brings riches brings also malaria'. Watson (1921) points out that 'Cromer insists that in Egypt, the success of irrigation depends no less on the channels for taking off the water than on the irrigation channels for its supply. It is notorious, too, that badly drained irrigated land is not only of less value agriculturally, but is also more malarious than irrigated land, where by means of an efferent system, the water on the land is more fully under control'.

Several workers have commented upon the harmful effects of water-logging in the Punjab. Christophers (1924) states that 'in the great Canal colonies, a serious menace is the malaria which is normally induced as the result of irrigation. At first relatively healthy, such areas are liable to an increasing malarial endemicity that, if it does not altogether nullify the good such schemes bring, at least detracts largely from this'. Gill (1930), in discussing the relationship of canal irrigation to malaria, states that 'it is certain that wherever canal irrigation gives rise to water-logging a vicious cycle is set up in which endemic malaria leads to bad health, bad health to economic stress and economic stress to further privation and sickness, and, finally, as the combined result of a high death rate, a low birth rate and emigration, to depopulation of the affected tract'.

King *et al.* (1929) have drawn attention to the serious results caused by water-logging following upon irrigation schemes in the Madras Presidency. The harm which may be done by such works has been emphasized by Rao (1929) who says—'It cannot, however, be too emphatically stated that the need for such irrigation works by no means implies the need to keep them in such an utter state of neglect as to be a constant source of danger to the general well-being. Even as the malaria investigator has got to view with sympathy the requirements of the agriculturist and the labours of the Revenue and the Public Works authorities on his behalf, the latter has equally to realize how necessary it is to ensure that the very facilities that are intended to give the ryot his daily bread do not act as his "death trap" as well. And it cannot be sufficiently brought home that a close collaboration between the two authorities would alone conduce to the optimum well-being of the people'.

From these authoritative statements, it is clear that the initial installation of a proper system of drainage in connection with all irrigation projects is essential, if the health of both the population and the land is to be preserved.

The need for such measures has been emphasized for many years. In certain provinces the vital necessity of such precautions has been realized, and the Water-logging Board of the Punjab (1930) have issued a statement of the 'principles to be observed in the preparation of canal projects and their execution'. Unfortunately, in connection with certain other large irrigation schemes initiated in recent years, the

results of the experience gained in the past, and repeated warnings, have passed apparently unheeded, with the result that the harmful effects of such ill-planned irrigation projects are already being felt, not only on the health of the people but on the agricultural value of the land (Sind). The conditions produced by a neglect of this principle are causing in India the loss of thousands of lives and crores of rupees annually, apart from the suffering of the population, the economic stress caused and the impoverishment of large tracts of valuable agricultural land.

Large sums of money are being spent in many parts of India in attempts to remedy the effects of a neglect of these principles, and these measures are almost certainly costing a much greater expenditure of money than would have been needed initially to prevent the occurrence of the damage. To this expenditure must be added also the losses due to the decreased revenue to the Government, the decreased prosperity of the population, the decreased fertility of the land and the decreased health of the people, which have already been caused by the neglect of proper precautions.

General remedies.—A proper consideration by an expert committee of the immediate and future results of such projects upon all aspects of the health and prosperity of the community, before schemes for any large engineering works are sanctioned. The committee should consist of expert representatives of the engineering, agricultural, financial, public health, and other interests likely to be affected by the work. The committee should formulate a scheme whereby the harmful effects of such an undertaking are prevented, and the cost of such preventive measures should be included in the estimate of the proposed engineering work. The preventive measures should be carried out before any harmful effects can be produced, and not delayed until these have already developed and become serious. As much attention should be given to measures for the removal of excess water as to the provision of water in irrigation schemes.

(2) *Increase in breeding places due to decrease of water*

In areas where, during the main malaria season, water is widespread like a sea, a marked decrease in the water surface leads to the formation of pools, with increased amount of water edge, and so an increased multiplication of mosquitoes. The great example of this in India would appear to be large areas of Lower Bengal. According to Bentley (1925), Willcocks, and many others, in the past these areas were covered by water from the Ganges—'inundation irrigation'—at certain seasons of the year. With the increase of embankments for the training of rivers, for roads, for railways, etc., this type of irrigation has been stopped, with the result that not only have the conditions for the

spread of malaria increased, but the land has become impoverished due to the absence of the valuable fertilizing silt which such water deposited. Bentley (1925), after a very careful study of the problem, came to the conclusion that these engineering works, usually built with the best intentions, have been responsible for conditions where 'agriculture, health and prosperity have suffered, millions of lives have been sacrificed, thousands of crores of rupees have been lost, the people are sunk in poverty and a vast proportion of them suffer each year from recurring attacks of malaria'.

General remedy.—The appointment of an expert commission to enquire into the causes of these awful conditions, and to formulate schemes whereby they can be ameliorated or eradicated, and prevented from increasing.

(B) *The introduction of human carriers of malaria into a healthy area, or of a relatively non-immune population into a malarious locality*

When any large industrial, engineering, mining or other project is undertaken in India, it is usually necessary to import labour for the work. These large 'aggregations of tropical labour' frequently suffer severely from malaria when introduced into a malarious area, or they may import malaria into a relatively healthy tract.

The incidence of malaria among these people, apart from its public-health importance, often produces serious difficulties in the labour problem. The completion of such large undertakings in the tropics is often hampered more by sanitary considerations than by engineering or industrial difficulties (Panama Canal, railway construction work, irrigation projects, mining industries, etc., etc.). In some instances, it has been found impossible to complete such works, or only at a very greatly enhanced expenditure, unless anti-malarial operations are actively undertaken (*vide* Sinton, 1936).

Apart from the effects of malaria upon the labourers themselves, the infection is liable to spread from these men to the inhabitants of the surrounding country, and to produce a high degree of prevalence or even epidemic conditions among them (docks at Bombay; railway construction in Rajshahi; roads in Burdwan, etc., etc.).

In addition to the immediate effects of such a spread of infection, the changes caused by engineering projects on the local physiographical and other conditions of the country, may lead to the continued prevalence or permanency of a high degree of endemicity of the disease (Burdwan district and many other parts of Bengal, water-logged areas in the Punjab, etc.). This is especially the case when such changes also give rise to economic stress, usually as the result of agricultural decline caused by the altered conditions.

General remedies.—The introduction of legislation to ensure proper sanitary and medical

arrangements in cases of 'tropical aggregation of labour', to prohibit the formation of conditions likely to affect the health of the local population, either temporarily or permanently, and to enforce measures for the abolition of any such harmful conditions as may be produced by these works.

(C) *Conditions leading to economic stress and lowered resistance of the population*

The appalling and tragic effects of malaria among certain aggregations of labour, where economic conditions are poor, and stress severely felt, have been fully described by Christophers and Bentley (1909). The sequence of events has also been pointed out by Sinton (1933).

The severe economic stress which follows upon water-logging has been described by many workers. Dempster (1848) and Taylor (1870) have given graphic descriptions of the miserable and malaria-stricken population who survived along the course of the old Western Jumna Canal, where water-logging, agricultural decline and economic stress prevailed. In more recent years, Gill (1922) and Lal and Shah (1933) have recorded a similar state of affairs in a water-logged area in the Punjab, while in the Madras Presidency, King *et al.* (1929) have drawn attention to such conditions at Mopad.

The relationship between impoverished soil, agricultural decline, economic stress and malaria has been emphasized by Bentley (1925) in relation to Bengal, and Fry (1914) speaks of the epidemics in certain areas of that province as 'deficiency epidemics'.

The conditions of economic stress with associated malarial prevalence mentioned above, have all been caused, either directly or indirectly, by large engineering or other works, and these have had a very adverse effect upon the health and prosperity of the people. Such conditions of economic stress have not only caused a rise in the direct mortality and morbidity due to malaria, but have also been responsible for increased sickness and death from other causes, among a population with a lowered resistance.

Discussion

While large engineering works in India, more especially those connected with irrigation and increased facilities for communication, have added much to the prosperity and wealth of certain parts of the country, in many instances they have been responsible for a great increase in the prevalence of malaria and economic stress in other areas. In some instances the end results have been so harmful as to annul almost completely the benefits which these works were intended to provide.

In the construction of large engineering works, the engineer naturally tries to complete the project as cheaply as possible, consistent with technical efficiency, and often takes no heed

of, or does not realize, the disastrous results to health and prosperity which may follow upon his operations. As has been truly remarked by Sir Malcolm Watson, 'engineering, which leaves a trail of malaria behind it, is bad engineering'.

The type of economy which gives rise to man-made malaria and agricultural decline is a false saving for any government, any department, or any commercial undertaking. The expenditure, which has to be incurred at a later date to ameliorate or remedy the harm caused, is usually very much greater than the initial outlay needed to prevent the damage. Apart from the public-health point of view, which is directly concerned with the mortality, the sickness and the suffering that these blunders cause before they are remedied, if this is ever properly done, there is the financial loss to the province or district in which they are allowed to occur. Many of these errors of omission and of commission have given rise, and are still giving rise, to agricultural decline, which must have cost the government and the community countless crores of rupees, and this apart from a great loss of efficiency among the labouring population of the malaria-stricken localities.

The urgent necessity for the institution of forceful measures to prevent the damage which is being done by man-made malaria in India, has been recognized for a very long time. Christophers and Bentley (1909) drew special attention to this factor in relation to 'tropical aggregation of labour'. Clemesha (1917), when Sanitary Commissioner with the Government of India, placed a memorandum before the Imperial Government, pointing out the evils which had arisen from the effects of certain large engineering works in India.

He stated that 'within the last decade, the science of epidemiology and preventive medicine have made enormous strides. Much of the work that has been done is naturally not known to Railway and Irrigation authorities and other large employers of labour, but the time has now come when co-ordination between these and the Sanitary Department is pre-eminently desirable'. He stresses the urgent necessity for the formation of expert committees to ensure such co-ordination.

The Hon'ble Mr. H. Sharp, Officiating Secretary to the Government of India, circulated Colonel Clemesha's remarks to all Local Governments and Administrations in 1919 (Sharp, 1919). He points out that questions connected with large aggregations of labour, the effect of borrow-pits and the interference caused by embankments upon the natural drainage of the country, had been engaging the attention of the Government of India for some time. He approved of the appointment of co-ordinating committees, and went on to say that the Railway Board have accepted these proposals, and 'the Government of India trust that similar steps will be taken in the case of public works under the control of the Public Works and other departments of Government'.

An executive order was passed by the Bengal Government in August 1921, in connection with new railway construction and anti-malarial work. Under this order before the actual construction of any new line was undertaken, a committee was to be appointed consisting of the Director of Public Health as Chairman, the Chief Medical Officer of the railway concerned, the Chief Engineer of the proposed construction and other important officers of the Civil Administration as members. This committee was to take note of the malarial conditions of the country through which the line was to travel; suggest the location of labour camps; and consider the subject of interference with natural drainage and the effect of borrow-pits on malaria. They were then to submit a report which would be sent finally to the Railway Board (Suhrawardy, 1928).

The 7th Congress of the Far Eastern Association of Tropical Medicine at their meeting in Calcutta in 1927 passed a resolution calling attention to the need for close co-operation between the public-health authorities and the engineers, in connection with such large engineering works in the tropics.

'The Malaria Section of the Seventh Congress of the Far Eastern Association of Tropical Medicine are aware of many instances of a great increase in the incidence of malaria caused by the facilities given to mosquito reproduction by engineering works, either during construction or afterwards, due to the different conditions brought about. This Congress is of opinion that plans of railways, canals, harbours and all similar engineering works likely to affect the conditions producing malaria should be submitted to the proper public-health authorities and their sanitary engineers before being sanctioned by Governments'.

A similar resolution was passed at the 12th Conference of Medical Research Workers at Calcutta in 1934.

'This Conference notes the rise of malaria that has occurred as the result of the Sind Irrigation Project and regrets that the definite early warnings of the Malaria Survey in this respect have apparently gone unheeded'.

'In future, in all provinces in India, before any irrigation or other major engineering projects are undertaken, there should be, where it does not already exist, compulsory co-operation between the Irrigation or other Departments concerned and the Public Health Department'.

The importance of the provision of proper sanitary precautions and the avoidance of operations likely to produce either a temporary or a permanent increase in malaria, cannot be too strongly emphasized either from the humanitarian, the financial, the labour or the agricultural standpoints.

The Panama Canal could not have been built but for the enforcement of anti-malarial measures of this kind, with which all other departments had to conform (Chamberlain, 1929). The success of the large works of agricultural 'bonification' in the malarious parts of Italy was hindered for many decades by the absence of such co-operation, and their full

benefits were only achieved when this was enforced (Ilvento, 1934). This has become so well recognized that legislation was passed to enforce it.

By the act of 1933, it was laid down that authorized schemes of 'bonification' must cover 'the planning, financing and operating not merely of hydraulic and agricultural works, but also the health services required to preserve the health of the labourers, peasants and superintending staff, without which every attempt must end in disaster. Such is the legal conception of the *bonifica integrale*' (Ilvento, 1934).

There are in India numerous examples of the good results which have followed upon the observation of these precautions in connection with large engineering works—the Raipur-Vizianagram line and some other railway projects, the Sara Bridge, the head-works of the Sarda Canal, the Mettur Dam, the Back-Bay Reclamation Scheme, Vizagapatam Harbour, to name but a few. Unfortunately, as can be seen from some of the examples cited earlier and those mentioned by Sinton (1935, 1935a), such essential measures are still being neglected in many places. There is still 'much of tragedy in the shape of lost opportunities, in the strangling hold of vested interests, in the stupidity, folly and pigheadedness, aye, and the wickedness, of those who oppose progress, who were deaf to the claims of science, who did their best to set back the clock' as an editorial in the *Lancet* (1924) expressed it.

One can understand perfectly the aim of the person responsible for such works, in attempting to get them carried out as cheaply as possible, in order to reflect credit on his department and to balance his budget. Unfortunately, the expenditure needed at a later date to remedy the harmful results produced, has to be found in the long run by the Government or other body concerned, and what was apparently a cheap job may become a very expensive one in money, mortality, morbidity, agricultural loss, economic stress and the many repercussions which these factors have upon the revenue and prosperity of the province or the community. Much of this wastage of money, men and material could have been avoided, if the after-effects had been foreseen and appropriate measures taken to prevent their occurrence.

The Governor of the Punjab, His Excellency Sir Herbert Emerson, in an address delivered this year (1935) at the opening of the Punjab Engineering Congress, points out the tendency of Government departments to look upon problems only from the aspect of how these affect the budgets of their own departments and not that of the province as a whole. He emphasizes the necessity of co-operation between different departments in the present and future interests of the finances of the provincial government as a whole and not that of their own departments only. He had instituted regular meetings between officers of all departments to

discuss problems of common interest, and he hopes that if co-operation is not established by certain officers 'the heads of the departments concerned will twist their tails to some effect'.

This lack of co-operation is affecting not only rural populations but also urban ones. The Malaria Commission of the League of Nations (1930), in the report of their tour in India, have called attention to the failure to deal with malaria in many Indian towns and cities.

'Although we adhere to our previous statement that rural malaria is the most important problem, we look upon it as a defect that the simple clear-cut conditions of urban malaria have not been controlled' (Malaria Commission, League of Nations, 1930).

The unsuccessful, or poor, results which have been reported in many parts of the world, when properly planned and feasible anti-malarial measures have been recommended, especially for urban areas, are, alas, too often due to the apathy, to the neglect, to the absence of co-operation, and even, in many instances, to the active opposition of either the non-official or the official populations, or both. The Malaria Commission suggest that, in some cases, the health and prosperity of the people have been sacrificed in the interests of political, religious, departmental, or other ends. The Royal Commission on Labour in India (1931) have also remarked upon the failure to undertake adequate anti-malarial operations, and Covell (1928, 1934) has noted upon this in relation to Bombay and Delhi. When these large and important cities are so backward, what can be hoped from smaller towns, if an example is not set for them?

'We need not insist on a history of all the attempts to carry out an efficient malaria control. Up to the present they have failed, not through want of sufficient knowledge or of means to carry them out, but through a deplorable lack of co-operation between the various authorities, through religious objections which must be respected in so far as they are sincere and not a weapon in the hands of politicians, and through agitation in certain sections of the Press, which would appear not to be aware of their great responsibilities' (Malaria Commission, League of Nations, 1930).*

'We have found only too often action on health matters ends with the holding of an investigation and the writing of a report, little effort being made subsequently to carry out even the simplest of its recommendations'† (Royal Commission on Labour in India, 1931).

This apathy and opposition have been felt in many more enlightened countries than India, and to overcome them very drastic steps have often been required.

'While public sentiment is still at sea, while our legislators, forgetting Beaconsfield's axiom that "the public health is the foundation on which reposes the happiness of the people and the power of the country",

*The Malaria Commission instance specially the cities of Bombay and Vizagapatam.

†A similar statement has been made by a Reviewer in the *Tropical Diseases Bulletin* (1935) in respect to New Delhi.

and ignoring his high challenge that "the care of public health is the first duty of a statesman", allow themselves to be duped or bribed into the support of movements against the public weal that would disgrace the dark ages, how can we hold up our heads in a scientific and cultured age?' (Wellman, 1913).

'As has been well said by the late William Edward Hartpole Lecky—"How different would have been the condition of the world and how far greater would have been the popularity of a strong monarchy if at the time when such a form of Government generally prevailed, rulers had had the intelligence to put before them the improvement of the health of the people and the prolongation of the lives of their subjects as the main object of their policy rather than military glory or the acquisition of territory or mere ostentatious or selfish display" (Hoffman, 1928). "Even the most stately grandeur is ineffective in subduing disease" (Celli, 1933).

'Even now malaria mosquitoes can be seen swarming in fairly thickly populated places simply because the inhabitants do not take the trouble to keep them down. It is generally the fault of municipal authorities. I certainly think that not enough discipline is exerted by British and European Governments to make local bodies in the tropics do their duty in this respect' (Mégroz, 1931).

This apathy, this neglect and this opposition are not only costing the local people and the nation very large sums of money through the continued prevalence of malaria (*vide* Sinton, 1935a), but have increased the expenditure required to carry out effective anti-malarial operations.

The widespread presence of man-made malaria is a very serious problem in India. In view of the enormous damage which this state of affairs has produced, and will produce in future, on the health and prosperity of the people of India, it appears to me that the time has come when all Governments and other bodies should pass, and *properly enforce*, appropriate legislation, regulations and rules to prevent the extension of this very serious evil. At the same time it should be made the duty of all those departments, bodies or persons responsible for the formation of such conditions, to be responsible also for the expenditure required to abolish them.

The expenditure needed for such work should be a legitimate charge upon the budgets of the departments or bodies responsible for the conditions, and *not* upon the Public Health or Medical budgets. The money available for the work of the latter departments is already too small to deal properly with the natural prevalence of malaria, without being further saddled with the burden of sickness, etc., produced through harmful and usually avoidable human activities.

A PRELIMINARY NOTE ON THE TREATMENT OF NEURO-SYPHILIS WITH MONKEY MALARIA

By R. N. CHOPRA, C.I.E., K.H.P., M.A., M.D. (Cantab.)
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

and

ASSISTANT SURGEON B. M. DAS GUPTA, L.M.P.
(From the School of Tropical Medicine, Calcutta)

KNOWLES and Das Gupta (1932) were the first to show that infection with a certain species of the monkey plasmodium could be transmitted to human beings. They infected three volunteers and found that in one the disease was extremely severe, in another it was of moderate intensity with a relapse, and in the third only a mild grade of intermittent fever resulted. Van Rooyen and Pile (1935) tried monkey malaria in the treatment of general paralysis of the insane on account of certain difficulties associated with the induction of benign tertian malaria for treatment of these cases in cold climates. They used a strain of *Plasmodium knowlesi* (Sinton and Mulligan, 1933) which they had transmitted to 12 human subjects. In all the patients on whom this treatment was tried, there was a good reaction followed by distinct improvement.

In November 1935, a patient suffering from optic atrophy with a history of syphilis and a moderately positive Wassermann reaction came to the senior author through Lieut.-Colonel E. O'G. Kirwan, I.M.S., Professor of Ophthalmic Surgery in the Calcutta Medical College, for treatment with malaria. In January 1936, a similar case with strongly positive Wassermann reaction was also admitted. As at this time suitable cases of benign tertian malaria were not available, it was decided to treat them both with the monkey plasmodium. The details of these cases are as follows:—

Case 1.—Hindu male, M. N. D., aged 36 years, was admitted to the Carmichael Hospital for Tropical Diseases on the 25th November, 1935, with dimness of vision and advanced optic atrophy. An examination of the blood showed a moderately positive Wassermann reaction. One eye was practically blind and in the other some central vision was left. On the 5th December, 1935, the patient was inoculated with *P. inui*. but up to the 3rd January, 1936, there was no rise of temperature and it appeared that infection had not taken place. On this date he was inoculated with 0.5 c.c. of blood from a *Silenus rhesus* monkey containing *P. knowlesi* (8,240 parasites per 1,000 leucocytes).

On the evening of the 18th January he first showed signs of getting a rise of temperature and on the 19th January an examination of the blood showed the presence of scanty rings. On the 20th and 21st of January the temperature rose to 102°F. with only slight remissions. On the 22nd January the temperature came down to 100°F. and the blood examination showed the presence of a few rings and growing trophozoites. On the 23rd and 24th of January the temperature kept up to 104°F. with slight remissions. On the 25th January it came down to normal in the morning but went up slightly in the evening. On the 26th January the temperature was normal and remained so. Examination of the blood on 29th January showed

BACTERIOLOGICAL STUDIES IN
EPIDEMIC DROPSYBy C. L. PASRICHA, M.A., M.B., B.Chir., M.R.C.S., L.R.C.P.

*Epidemic Dropsy Research Worker under the Research
Fund Association**(An enquiry at the School of Tropical Medicine,
Calcutta, financed by the Indian Research Fund
Association)*

WE do not propose to review the mass of literature on the ætiology of epidemic dropsy. A selected and useful bibliography is given at the end of Chopra and Chaudhuri's (1935) report of an outbreak of epidemic dropsy in Purulia and Chopra and Bhattacharya's (1935) paper in the same number of the journal.

The one important fact that has emerged from the many studies that have been undertaken into the causation of epidemic dropsy is that rice is associated with the outbreaks of this disease. Acton (1922) first suggested that it is the infection of the rice that plays an important part in the ætiology of epidemic dropsy. Three years later Acton and Chopra (1925) described the infection of rice grains by spore-forming proteolytic bacilli belonging to the *vulgatus* group. The infection of rice grains was more liable to occur during the hot humid months of the monsoon, especially if the rice was stored in non-ventilated rooms. These workers held that certain poisonous water-soluble and thermostabile bases elaborated in diseased grains were responsible for the signs and symptoms of the disease. In 1927 these two workers reported the presence of Gram-positive bacilli in the stools of cases.

The evidence implicating the spore-forming bacilli, though strong, was not conclusive. An outbreak of epidemic dropsy in September 1934 gave us an opportunity to reinvestigate the subject.

The results of this inquiry are recorded in two parts: the first dealing with the bacteriological studies of the cases of epidemic dropsy and the second summarizing the results of the examination of samples of rice from different sources.

(A) *Bacteriological study of cases of epidemic dropsy*

Careful bacteriological investigations were made of every case admitted to the Carmichael Hospital for Tropical Diseases. Material for examination was also collected from certain isolated outbreaks of the disease in Purulia and elsewhere. The examination included:—

(1) Bacteriological examination of blood was made in 77 cases. The blood was collected in two flasks of glucose broth. One flask was incubated aerobically and the other under anaerobic conditions. The flasks were kept under observation for three months. No organisms were isolated from any of the samples. In five samples contamination of the medium occurred after two months' incubation. The time of collection of samples of blood in relation to the duration of the disease is shown below.

TABLE I

Showing the time after onset of the disease that the blood of epidemic dropsy cases was bacteriologically examined

Period after onset of disease	Number of patients in whom blood cultures were made
One week	3
Two weeks	2
Three "	6
Four "	39
Six "	4
Eight " or over ..	23
TOTAL ..	77

It will be seen that the majority of the blood cultures were made a month after the onset of the disease. This is due to the fact that the cases do not seek admission into hospital till the symptoms are well established. All the cases, however, showed active symptoms of the disease and some were pyrexial when the blood was collected.

In view of the paucity of the number of cases examined during the early stage of the disease the results obtained have only limited value. They do show, however, that even in protracted cases or cases in which frequent exacerbations occur, no organisms are found in the blood. This confirms Acton's findings.

(2) Catheter specimens of urine from sixty cases of epidemic dropsy were examined. The urine was collected during different stages of the disease and incubated in the same manner as the blood samples. In addition each sample of urine was incubated by itself and any growth plated out on Conradi's medium as well as MacConkey's neutral-red bile-salt lactose agar and nutrient agar. In about 10 per cent of the samples streptococci, mainly of the viridans

no parasites. No antimalarial treatment was given to this patient and the infection appeared to have died out spontaneously.

On the 31st January, this patient was re-inoculated with 0.8 c.c. of blood containing *P. knowlesi* (4,200 parasites, chiefly growing trophozoites and schizonts, per 1,000 leucocytes). No infection, however, resulted till the 16th February, when he was again given 4 c.c. of blood showing scanty rings from a patient experimentally infected with *P. knowlesi*. Up to the time of writing (26th February), there has been no rise of temperature and the examination of blood has shown no parasites.

The general condition of the patient has improved and he says that his vision is distinctly better. The patient was, however, examined by the ophthalmologist who reported that there was no change so far as the fields of vision and the condition of the retina were concerned. Whether by this treatment further progress of optic atrophy has been checked or not remains to be seen. The patient is under observation.

Case 2.—Mohammedan male, K. T. N., aged 25 years, had suffered from defective vision since 1926. From January 1934 to January 1935 he had four or five transient attacks of facial paralysis and there was rapid deterioration in the eyesight. The patient was examined by Lieut.-Colonel Kirwan, I.M.S., who found fairly advanced optic atrophy and referred him to the senior author for treatment with malaria. On admission the patient looked apathetic, gait somewhat spastic, pupils slightly dilated, reaction to light sluggish, the knee-jerks were dull, Babinski's sign present, ankle clonus absent, Romberg's sign absent and the speech was blurred and understandable with great difficulty. The mental condition of the patient was peculiar. He could answer questions intelligently sometimes, but often was very dull and could hardly comprehend anything. He was irritable and was upset on the slightest provocation. Examination of the blood showed the Wassermann reaction strongly positive.

On the 30th January, 1936, the patient was inoculated subcutaneously with 0.8 c.c. of blood from a *Sileneus rhesus* monkey infected with *P. knowlesi* (4,200 parasites, chiefly growing trophozoites, per 1,000 leucocytes). On the 6th and 7th February the patient had a cold in the head and had a slight rise of temperature which persisted from 8th to 11th February. No malarial parasites were found in the blood. Between the 11th and 13th February the temperature was normal but it started rising again on the 14th February. Examination of the blood on the 16th February showed the presence of a few rings; on the 17th February a few rings and scanty mature schizonts were present; on the 18th February 426 parasites—rings, growing trophozoites, developing schizonts and scanty gametocytes—per 1,000 leucocytes were present. The temperature rose to 104.6°F. and in the afternoon the patient became semi-conscious, had a good deal of rigidity of the neck, and could be roused with difficulty. In the evening the patient's condition became alarming and 0.1 gm. of atabrin was given by the mouth. In a few hours the patient's general condition was reported to be very much improved; he became conscious and the rigidity of the neck passed off. On the morning of the 19th February the patient was seen again by the senior author and it was found that the condition was similar to that found on the previous day and it appeared that he was passing into a semi-comatose state. There was also a marked yellow coloration of the skin. The temperature was 102.6°F. and blood examination showed the presence of 629 parasites (almost all phases) per 1,000 leucocytes.

As the patient had shown sensitiveness to atabrin 0.5 gm. of quinine was given by intramuscular injection. Within a few hours of the injection the temperature came down. On the 20th February the temperature came down to normal and all the symptoms passed off. The change in the condition of the patient was very remarkable. The rigidity in the neck

passed off, the patient became quite alert, answered questions intelligently and said he was much better. Examination of the blood at this stage showed a few trophozoites showing evidence of degeneration. On the 21st February scanty trophozoites in a marked state of degeneration were visible in the peripheral blood. On the 22nd February no parasites were seen in thick films.

Discussion.—The first patient showed a marked refractoriness to infection with *P. knowlesi*. After the initial inoculation there was a long incubation period, the temperature was never high and the infection died out spontaneously within a week. A second injection of 0.8 c.c. of blood was tried without infection resulting, whereas the same dose from the same animal given to another patient at the same time produced alarming symptoms. The complete failure of the second injection may be ascribed to a degree of tolerance being acquired by the patient on account of the previous infection.

The interesting points about the second case are high temperature with low parasite count similar to that seen in quartan infection, and the development of marked cerebral symptoms which were easily controlled with small doses of atabrin and quinine. It is too early to say yet how the condition of the eyes has been affected by the treatment, but there is no doubt that the reaction of the pupils to light is more brisk and the mental condition of the patient has greatly improved. He is no longer apathetic and is now demanding to go to his home and to his people. His speech though still blurred is clearer than before. An examination by the ophthalmic surgeon on the 26th February showed that so far as the fields of vision and the appearance of the retina are concerned there is no change. The patient is being kept under observation.

It may further be stated that it appears that an attack of monkey malaria in human subjects confers immunity or a marked degree of tolerance to re-infection. How long this tolerance is maintained is now being studied.

Conclusions.—Inoculation with *Plasmodium knowlesi* places in the hands of the clinician a good method of malarial therapy in the treatment of neuro-syphilis. It produces well-marked reactions which can be easily controlled by antimalarial drugs and is free from many of the disadvantages accruing from the treatment with ordinary benign tertian infection transmitted either by mosquitoes or by injection of the infected blood. A large number of patients will, however, have to be treated with this form of therapy before its value can be properly adjudicated.

*Epidemic Dropsy Research Worker under the Research
Fund Association**(An enquiry at the School of Tropical Medicine,
Calcutta, financed by the Indian Research Fund
Association)*

WE do not propose to review the mass of literature on the ætiology of epidemic dropsy. A selected and useful bibliography is given at the end of Chopra and Chaudhuri's (1935) report of an outbreak of epidemic dropsy in Purulia and Chopra and Bhattacharya's (1935) paper in the same number of the journal.

The one important fact that has emerged from the many studies that have been undertaken into the causation of epidemic dropsy is that rice is associated with the outbreaks of this disease. Acton (1922) first suggested that it is the infection of the rice that plays an important part in the ætiology of epidemic dropsy. Three years later Acton and Chopra (1925) described the infection of rice grains by spore-forming proteolytic bacilli belonging to the *vulgatus* group. The infection of rice grains was more liable to occur during the hot humid months of the monsoon, especially if the rice was stored in non-ventilated rooms. These workers held that certain poisonous water-soluble and thermostable bases elaborated in diseased grains were responsible for the signs and symptoms of the disease. In 1927 these two workers reported the presence of Gram-positive bacilli in the stools of cases.

The evidence implicating the spore-forming bacilli, though strong, was not conclusive. An outbreak of epidemic dropsy in September 1934 gave us an opportunity to reinvestigate the subject.

The results of this inquiry are recorded in two parts: the first dealing with the bacteriological studies of the cases of epidemic dropsy and the second summarizing the results of the examination of samples of rice from different sources.

(A) *Bacteriological study of cases of epidemic dropsy*

Careful bacteriological investigations were made of every case admitted to the Carmichael Hospital for Tropical Diseases. Material for examination was also collected from certain isolated outbreaks of the disease in Purulia and elsewhere. The examination included:—

(1) Bacteriological examination of blood was made in 77 cases. The blood was collected in two flasks of glucose broth. One flask was incubated aerobically and the other under anaerobic conditions. The flasks were kept under observation for three months. No organisms were isolated from any of the samples. In five samples contamination of the medium occurred after two months' incubation. The time of collection of samples of blood in relation to the duration of the disease is shown below.

TABLE I

Showing the time after onset of the disease that the blood of epidemic dropsy cases was bacteriologically examined

Period after onset of disease	Number of patients in whom blood cultures were made
One week	3
Two weeks	2
Three "	6
Four "	39
Six "	4
Eight " or over ..	23
TOTAL ..	77

It will be seen that the majority of the blood cultures were made a month after the onset of the disease. This is due to the fact that the cases do not seek admission into hospital till the symptoms are well established. All the cases, however, showed active symptoms of the disease and some were pyrexial when the blood was collected.

In view of the paucity of the number of cases examined during the early stage of the disease the results obtained have only limited value. They do show, however, that even in protracted cases or cases in which frequent exacerbations occur, no organisms are found in the blood. This confirms Acton's findings.

(2) Catheter specimens of urine from sixty cases of epidemic dropsy were examined. The urine was collected during different stages of the disease and incubated in the same manner as the blood samples. In addition each sample of urine was incubated by itself and any growth plated out on Conradi's medium as well as MacConkey's neutral-red bile-salt lactose agar and nutrient agar. In about 10 per cent of the samples streptococci, mainly of the viridans

type, and a variety of other intestinal organisms were obtained. A few samples showed the presence of spore-forming bacilli but these were few and the findings irregular so that it was impossible to exclude extraneous contamination.

(3) Repeated cultural examination of the stools of 117 epidemic dropsy cases were made. The stools were plated on MacConkey's neutral-red bile-salt lactose agar and ordinary nutrient agar. Duplicate sets of plates were made and incubated under aerobic and anaerobic conditions. In all plates, but more abundantly on nutrient agar than on MacConkey's medium, colonies of Gram-positive spore-forming bacilli were found. As these colonies grew readily under aerobic conditions and more slowly under anaerobic conditions, the anaerobic method of cultivation was later abandoned.

It may be noted that in a small proportion of cases, a variety of non-lactose-fermenters were also found, but, as these organisms belong to the usual type of non-lactose-fermenters found in other hospital cases, no importance can be attached to these findings. Stools from 200 cases not suffering from epidemic dropsy and with no history of the disease were examined as controls. The results of these examinations are summarized in table II.

TABLE II

Showing the frequency of the finding of spore-forming bacilli in the stools of epidemic dropsy cases during different stages of the disease and the results of the examination of the stools of a control series of 200 individuals not suffering from epidemic dropsy

Type of case	Number examined	Number in whom spore-forming bacilli were isolated	Percentage positive
Epidemic dropsy during the first two weeks of the disease.	7	7	100
Epidemic dropsy from the 2nd to the 8th week of the disease.	106	103	97
During convalescence.	4	1	25
Control series of non-epidemic-dropsy individuals.	200	18	9

There was not a single case of epidemic dropsy in which we failed to isolate spore-forming bacilli in the early stages of the disease and for a period of two months after the onset spore-forming bacilli were recovered from almost all the cases.

In a certain number of the cases particularly with diarrhoeic stools, the plates inoculated with stools showed a very great preponderance of colonies of spore-formers. The number of convalescent cases examined is far too small for the results to have any significance. Spore-formers were recovered in 9 per cent of the control series of 200 individuals. It was impossible to obtain in the control series satisfactory histories to exclude contact with epidemic dropsy cases. The preponderance of Gram-positive bacilli was also noted in smears prepared from the stools of epidemic dropsy cases.

The spore-forming bacilli isolated from the stools of epidemic dropsy cases are similar in their main characteristics to the organisms described by Acton. The majority of the strains ferment glucose, maltose and saccharose with the production of acid only. Some strains are late fermenters of mannite and about 10 per cent of the strains ferment lactose. All the strains examined liquefy serum, agar and rice 'conji' medium and peptonize milk. They do not constitute a homogeneous group but differ both biochemically and serologically. In this present communication it is not proposed to go into the description and classification of the strains.

In order to incriminate, in the causation of epidemic dropsy, any of the strains of spore-forming bacilli isolated from the stools we examined sera of a number of cases for the presence of specific agglutinins. Four strains isolated at the beginning of the epidemic were found to be well agglutinable by the sera of epidemic dropsy cases. Table III summarizes the results of the examination of sera of epidemic dropsy cases for the presence of agglutinins against these organisms. Table IV shows the results of a similar examination of sera from individuals not suffering from epidemic dropsy. It might be stressed here that the control series of sera were obtained from individuals as far as possible of the same stratum of society as the cases themselves. It was impossible in many instances to obtain reliable histories excluding a previous attack or contact with actual cases.

It will be seen that although agglutinins for these organisms are present in a certain proportion of individuals not suffering from epidemic dropsy, the percentage and titres are much higher in the sera of epidemic dropsy cases. The number of sera examined are too few to justify any definite conclusions but the tentative conclusions arrived at during the course of this work are :—

(1) The agglutinins increase in amount as the patient becomes convalescent followed later by gradual decline in the titre.

(2) Agglutinins are present in cases of epidemic dropsy occurring in widely separated places.

TABLE III

7,708	60	3.3
7,427	60	1.6	1.6

(3) Agglutinins are not present for other intestinal organisms picked up from epidemic dropsy stool plates.

(4) 'O' agglutinins were found in dilutions of 1 in 500 in three of the 5 cases where they were looked for. In the few control sera examined 'O' agglutinins were absent.

(5) Agglutinins for these organisms were not found in the five samples of fluid removed from the eye in cases of glaucoma due to epidemic dropsy, whereas they were present in the serum of these cases.

(6) In the few healthy individuals examined at the beginning of the epidemic and in individuals who do not eat rice or eat it only occasionally, agglutinins for the spore-forming bacilli were not found.

Unfortunately, owing to the cessation of the epidemic, it was not possible to continue this work. The results recorded above, however, fully confirm Acton's work. The development of agglutinins against spore-forming bacilli is additional evidence in support of the incrimination of these spore-formers in the aetiology of epidemic dropsy. It is however possible that these organisms are associated with the disease in the same manner as the proteus group of organisms are with typhus fever.

Various experiments designed to reveal anything of the nature of a filtrable virus were performed. Filtrates of ground-up sarcoids were injected into animals and man but with negative results.

Serum from convalescent and recovered cases of epidemic dropsy when injected intradermally in cases with well-marked erythema showed no blanching of the skin.

Filtrates of stools from epidemic dropsy cases cause slight but definite flocculation of convalescent serum. This flocculation was not obtained with filtrates of stools from healthy individuals. This work is in progress and is being extended to filtrates obtained after the growth of the implicated organisms in different media.

(B) *The study of rice associated with and not associated with outbreaks of epidemic dropsy*

A very large number of samples of rice were collected from sources associated with outbreaks of epidemic dropsy and not associated with outbreaks of epidemic dropsy. The latter were obtained from places where there were cases of epidemic dropsy but no evidence of the implication of the particular samples of rice with the disease and from areas free from the disease. The methods of examination of the samples of rice were on the same lines as those adopted by Acton and are outlined below:—

(1) Naked-eye appearance for the quality, grade and infection of the rice sample.

(2) 'Water-test' for the presence of opacity in the grain.

(3) Bacteriological for the isolation of organisms from the infected grains.

Summary of the method employed:—

(a) Infected grain placed in commercial formalin for five minutes.

(b) Grains washed repeatedly with saline and, allowed to remain in saline for two hours. This last is to soften the grain to facilitate the subsequent cutting.

(c) The grains are cut with a sterilized scalpel and planted with the cut surface to the medium (nutrient agar). On one half of the plate whole grains are planted in rows. This latter serves as a control of the efficient sterilization of the surface of the rice grain.

Good growth is usually obtained within 48 hours. The plates were incubated and observed for a week.

Table V shows the results of the examination of rice collected from houses (a) where there were cases of epidemic dropsy and (b) not directly associated with epidemic dropsy.

This is also shown graphically below.

Tables V and VI and the graph show that the incidence of epidemic dropsy is associated with the consumption of diseased rice. Rice showing greater degrees of infection are associated

with a larger number of actual cases of the disease.

GRAPH TO TABLE VI

Fifty-seven samples of rice were obtained from Rangoon; 41 of these were from houses where there were cases of epidemic dropsy and

7	1	..	A	A	A	A	A	A

TABLE IX
Showing the percentage of sera from epidemic dropsy cases agglutinating at specified titre the spore-forming bacilli isolated from infected rice as compared with sera from healthy individuals

Sera from	Number examined	TITRE			
		1 in 25 and over	1 in 50 and over	1 in 100 and over	1 in 200 and over
Epidemic dropsy cases	26	80.7	65.3	34.6	19.2
Healthy individuals ..	25	48.0	32.0	12.0	0.0

macroscopic evidence of infection in the form of a central opacity in the rice grain is also to be seen in many of the imported rices. There is tentative evidence to suggest that the infection in these samples is by a different group of soil or plant bacteria.

The bacilli isolated from infected rice grains are similar to those isolated from epidemic dropsy cases. They all liquefy gelatin, serum, agar and rice 'conji' medium and peptonize milk. The fermentation reaction of 42 'rice' strains studied is given in table VIII.

Representative strains from the group containing the largest number of strains were selected for agglutination with the sera of epidemic dropsy cases and as a control with sera of healthy individuals. The results are shown in table IX.

These results show the presence of agglutinins both in the epidemic dropsy cases and in the control healthy individuals belonging to the same social group as the epidemic dropsy cases. The frequency is, however, much greater in the epidemic dropsy cases.

Conclusions and Summary

The bacteriological findings in epidemic dropsy described by Acton and Chopra were fully confirmed by our results. Gram-positive spore-forming proteolytic bacilli were found in stools of every case of epidemic dropsy and similar organisms were found in infected rice grains.

These organisms are heterogeneous in their biochemical and serological properties. A good deal of work still remains to be done before the identity of these Gram-positive spore-forming bacilli is definitely established.

We have presented evidence to show that agglutinins against these organisms develop in cases of epidemic dropsy. Such agglutinins are also to be found but in much lower titre and not so frequently in apparently healthy individuals in Calcutta. The frequency of such agglutinins in different communities such as rice-eaters and non-rice-eaters still remains to be determined. From the few cases that we have examined there is evidence to suggest that such agglutinins are not present in non-rice-eaters.

These serological findings are an additional link in the chain of evidence to show that epidemic dropsy is of an infective nature and is associated with the presence of certain organisms in rice grains. It is possible however that the rôle played by these organisms in the ætiology of the disease is of the same nature as that of the proteus group of organisms in typhus fever.

IN 1929 d'Harcelle, Malone and Lahiri (1930) described very clearly three different races of cholera phage and as their work has been overlooked by subsequent workers we give verbatim the original account of these workers. 'One race of bacteriophage might provoke complete clearing of the medium; in another race the action might be slower and clarification complete only after 12 or 24 hours; in yet another race the action might only be partial, a portion only of the vibrios being destroyed and the medium not even noticeably cleared. Between total destruction of the vibrios in two hours and a destruction so weak that it must be anticipated to be perceived all intermediate stages can be found'. This account of three races of cholera phage is applicable in its entirety to the types A, B and C described a year later by Asheshov (1930). Two years later, we (1932 and 1932a) reported three further types (D, E and F) which were soon followed by types G, H and J reported by Morison (1933), and type K by ourselves. Type L was added to the list of cholera phage types by Anderson in 1935.

Asheshov, Asheshov, Khan, Lahiri and Chatterji (1933) gave a brief description of the five different types of cholera phages then existing. We are not aware of any detailed description of the types of phages since described. Some of the types are still incompletely studied, particularly types H and L which possess certain peculiarities in that they are difficult to propagate and filter.

The one characteristic of all types of cholera phage is that they possess reciprocal action; the secondary cultures obtained after the action of any one type is lysable by the remaining types of cholera phages. To the 11 types of cholera phage (A to L) which possess this characteristic reciprocal action we have added another type which we have called type M.

Isolation of cholera phage type M

Strain no. 609/C.H./1935—an inagglutinable strain from a cholera case which was resistant to all the known types of cholera phage—was found to be weakly lysable by our mixture of samples of natural phages collected during the latter half of the year 1935. This phage was enhanced and purified by repeated passage and isolation on this strain. It was then found to lyse a culture of agglutinable cholera vibrios made resistant to all the known types A to L.

Characteristics and properties of cholera phage type M

Cholera phage type M is a slow-acting bacteriophage which gives an incomplete lysis in liquid medium. On solid medium it acts

Photograph showing the varying size of plaques formed by cholera phage type M. The photograph has been enlarged $2\frac{1}{2}$ times.

well giving rise to definite clearing and an undermined edge, secondary colonies appear readily and in 48 hours the clearing produced by phage action is almost filled up with the secondary culture. The plaques formed are extremely minute, undermined and smaller than those formed by type A. There is a very great tendency for variation to occur in the size and characters of the plaques (*vide figure*). It may be noted that this tendency to variability in plaque formation is not peculiar to this type of cholera phage but occurs with other types of cholera phages as well though not so readily.

This bacteriophage acts both on rough and smooth vibrios and has a very wide range of activity. All ultra-pure cholera vibrios are lysed by it. It also acts on a large proportion of aberrant agglutinable vibrios and on 7 per cent of the 288 inagglutinable vibrios tested. Its rate of multiplication is $n \times 10^1$ in two hours. The maximum multiplication being $n \times 10^{10}$. From the number of cholera cases examined during the inter-epidemic period this type was not found. Its frequency in Nature has not as yet been determined.

With the addition of type M we have 12 different types of cholera phage each of which possess the property of reciprocal activity. Although they all act on ultra-pure cholera vibrios, they vary considerably in the effects they produce singly or in combination. Of the 12 types described so far there is only one type—type A—whose action is restricted to agglutinable vibrios only and of these only the ones which possess a considerable amount of smooth element. All the other types (types B to M) lyse a certain number of inagglutinable vibrios. Certain of these types bring about marked changes in the antigenic structure of vibrios. Smooth strains are turned rough or the reverse change can occur, and agglutinable strains become either only partially agglutinable or completely inagglutinable.

From some of our own unpublished observations we have found that type A stands out from all other types in being antigenically distinct. Type A antiphage serum inhibits only type A cholera phage whereas the other types appear to be related serologically. With the addition of new types this work has to be repeated and the previous results revised and amplified. We have in cholera phage a bacteriophage which has been studied in considerable detail. It has already been resolved into 12 component types, a study of which will considerably advance our knowledge of bacteriophage. Added to the twelve types of cholera phage we have a number of races of vibriophages, using the term vibriophage for those phages which are active on inagglutinable vibrios and which if active on agglutinable vibrios do not give the reciprocal cross test. These in themselves deserve very careful study. We (1932a) have already shown that under the influence of certain races of vibriophages, some strains of inagglutinable vibrios acquire the property of agglutinability and become indistinguishable from the so-called authentic cholera vibrios. It cannot be stressed too strongly that in any bacteriological study of vibrios cholera phages and vibriophages must play an important rôle.

Summary

A new type of cholera phage—type M—is described. The importance of bacteriophage in the study of vibrios is stressed.

DESCRIPTION OF *BACTERIUM* *PSEUDO-CAROLINUS*

By C. L. PASRICHA, M.A., M.B., B.Chir., M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

Professor of Bacteriology and Pathology
and

G. PANJA, M.B., D.B.

Assistant Professor of Bacteriology
(From the Bacteriological Department, School of
Tropical Medicine, Calcutta)

THE records of the routine work carried out in the bacteriological laboratory of the School of Tropical Medicine during the past nine years show that the commonest non-lactose-fermenting bacilli isolated from stools resemble

1917 (Castellani and Chalmers, 1919). An analysis of the intestinal non-lactose-fermenters isolated during 1934 extracted from the report of the department (Pasricha, 1935) is a typical example of the findings each year.

The 3,675 specimens of stools examined from the Carmichael Hospital for Tropical Diseases were collected from 1,220 inpatients. Very few of the patients were suffering from acute bacillary dysentery; the majority of the patients were suffering from vague abdominal symptoms or were those in whom the clinical condition was suspected to be due to some intestinal infection. From the 3,675 specimens examined we isolated non-lactose-fermenting organisms from 691 samples. The number of times and the

number of cases from which these organisms were isolated is shown in the above table.

These figures cannot be taken to represent the real incidence of bacterial infections in Calcutta, but they give an idea of the comparative frequency of the different organisms. Nearly 30 per cent of the patients admitted into the hospital for various diseases were found to pass non-lactose-fermenting bacilli. The organism most frequently found in the samples was *Bact. pseudo-carolinus*.

Attention has been drawn repeatedly to the frequency of the association of this bacillus to various conditions, from acute dysentery to vague abdominal symptoms. We have found this organism in almost pure culture in some cases of acute dysentery in which, in spite of repeated search, no other causative organism was isolated. Acton (1928 and 1929) and Acton and Knowles (1928) found this organism frequently in cases of sprue and chronic intractable dysentery. In 1929 and again in 1930 Acton (1930 and 1931) reported extremely good results in the treatment of cases of chronic colitis with autogenous vaccines of this organism.

One of us (Pasricha, 1931) recorded an experiment in which an agglutinable *Bact. flexneri* strain, after the action of bacteriophage, lost the property of agglutinability with *flexneri* specific serum and the secondary colonies fermented glucose, mannite and maltose with the production of acid and gas. A strain of *Bact. flexneri* had under the influence of bacteriophage acquired the fermentative properties of *Bact. pseudo-carolinus*. A year later Acton (1932) reported that, in certain cases of acute dysentery in which *Bact. flexneri* had been isolated during the early stages of the disease, *Bact. pseudo-carolinus* was found during the later stages, and that such findings were more frequent in those cases in which bacteriophage had been used therapeutically.

In 1933, one of us (Pasricha, 1934) reported that certain variants of *Bact. flexneri* produced after the action of bacteriophage resembled *Bact. pseudo-carolinus*, not only in their biochemical reactions but also that certain variant colonies exhibited serological similarity.

Chopra and Chaudhuri (1934) analysed a series of 40 cases in which from the clinical evidence and the results of vaccine therapy they concluded that this organism played an important part in the production of symptoms.

These records, which we have briefly referred to, are all from the work carried out at the School of Tropical Medicine. We are not aware of any other work dealing either with the study of this organism or its association and implication with diseased conditions.

In the table of aerobic asporogenous intestinal bacilli Castellani describes *B. pseudo-carolinus* as non-motile, Gram-negative, indol-positive, Voges-Proskauer-negative, and fermenting the following sugars with the production of acid and gas:—glucose, mannite, maltose, raffinose, arabinose, galactose, levulose, and sorbite with the production of acid only. It does not ferment lactose, saccharose, dulcitol and inulin, and it produces no change in litmus milk and no liquefaction of serum and gelatin. Castellani in the same table gives a description of another organism which differs from his *B. pseudo-carolinus* in that it is motile. This last organism Castellani placed in the genus *Salmonella* and classified it in the paratyphoid-asiaticus group. Because of the indol production he placed it in the asiaticus division of this group. *B. pseudo-carolinus* would be placed in the same group but differentiated from *B. carolinus* in that it is non-motile whereas *B. carolinus* is a motile organism. Castellani has not described, as far as we are aware, the serological properties of *Bact. pseudo-carolinus*, nor assigned any pathogenic effects to this organism.

We have not found any reference to this organism in literature except that outlined above, and Bergey (1934) does not include any description of this organism. Since this organism is one of the commonest non-lactose-fermenting

intestinal organisms found in Calcutta and evidence is accumulating to show that it possesses pathogenic properties, it is essential that a description of this organism should be recorded and, in the light of modern knowledge, its systematic position determined.

We selected 42 strains which, on isolation, gave the biochemical reactions similar to Castellani's *Bacillus pseudo-carolinus*, or as we would prefer to call it *Bacterium pseudo-carolinus*. It should be noted here that the reading of 'sugar' fermentation after 24 hours' incubation, as is usually done in diagnostic laboratories, is not sufficient to differentiate this organism. To illustrate this point we selected a series of 70 strains which, after 24 hours' incubation, gave the 'sugar' reactions of *Bact. pseudo-carolinus*. On further incubation, 28 of these strains fermented lactose with the production of acid or acid and gas. The majority of these 28 strains fermented lactose within 72 hours, the rest within five days. These late lactose-fermenters were not included in our series.

Of the 42 patients from whom this organism was recovered, only a few were suffering from acute dysentery with typical blood and mucus in the stools, the majority of the patients had vague abdominal symptoms and a few no symptoms referable to the intestinal canal. Agglutination tests with their serum against the homologous organism were carried out in 26 cases; 19 were negative, two showed agglutination in dilution of 1 in 25, two in 1 in 50, two in 1 in 100, and one in 1 in 320.

The 42 strains fall into three main groups as judged by their fermentative properties. Minor variations occur when a large number of test carbohydrates are used but with the 'sugars' generally used (lactose, glucose, mannite, maltose, dulcitol, saccharose, salicin in peptone water with Andrade's indicator and litmus milk) three main biochemical groups can be differentiated.

All the strains fermented glucose, maltose and mannite in 24 hours producing acid and variable amounts of gas. Nine of the 42 strains gave acid and gas production in salicin after 48 hours, but within seven days. Fourteen per cent of the strains fermented dulcitol, but often late. These fermentative properties proved constant at re-examination carried out several times during the two years that these strains have been under observation. On the basis of the fermentation reactions the strains form a single group with a few strains that are late fermenters of dulcitol or salicin. A brief description of the organism is given below.

Description of Bact. pseudo-carolinus

The bacilli resemble *Bact. coli* in shape and size and are arranged singly, in pairs, or in short chains. There are no spores, no capsules and the bacilli are non-motile (tested in fluid medium after varying periods of growth). They

stain easily with ordinary aniline dyes, are Gram-negative and non-acid-fast. On nutrient agar plate, after 24 hours' growth at 37°C. the colonies are round, greyish-white, opaque, amorphous in structure about 2 mm. in diameter with smooth glistening surface, and an entire edge. The emulsifiability of a colony is easy. After seven days the colonies increase to about 1 cm. in diameter and the edge is often markedly lobulated with radial striation from the centre. This lobulation occurs more readily on MacConkey's medium and is often marked within 48 hours. Lateral offshoots are sometimes present. In some strains, particularly old laboratory strains, rough variants develop. On nutrient agar slope, after incubation at 37°C. for 24 hours, there is a luxuriant growth resembling that of *Bact. coli*.

In broth there is a copious growth with uniform turbidity and a slight viscid sediment. There is no surface growth in the majority of the strains; in some strains a powdery pellicle develops. There is no odour.

In glucose-agar-shake after 24 hours there is disruption of the medium and the medium is driven up to the plug. On gelatin and Læffler's serum, good growth is obtained but no liquefaction of the medium occurs. On potato there is a colourless confluent growth.

It is an aerobic and facultative anaerobic organism. There is no lysis of sheep or rabbit's red cells. The majority of the strains ferment glucose, maltose, mannite, arabinose, galactose, lævulose with the formation of acid and gas and sorbite with the production of gas only. It produces no change in lactose, saccharose, inulin, inosite and raffinose. A few strains ferment in addition salicin, dulcitol or xylose with the formation of acid and gas. It produces an initial slight acidity in milk which in three to seven days becomes alkaline. There is no clotting of milk. It forms indol; Voges-Proskauer reaction is negative; methyl-red is positive; nitrates are reduced; methylene blue is partially reduced; hydrogen sulphide and ammonia are not produced; and it gives a marked catalase reaction.

Experimentally *Bact. pseudo-carolinus* kills mice within five days when injected in 1 c.cm. dose (approximately 2×10^9 organisms) of a killed culture intraperitoneally. A similar dose of *Bact. flexneri* kills in two to three days.

By agglutination and absorption tests this organism shows no antigenic relationship to the other known organisms in the *Salmonella* group. Serologically it is extremely heterogeneous, sera prepared with strains agglutinate the homologous strains only. Although by direct agglutination tests it shows no relationship to *Bact. flexneri* under suitable methods of cultivation but under the action of bacteriophage it shows distinct antigenic relationship to *Bact. flexneri*.

We have already referred to the changes induced in a strain of *Bact. flexneri* in which after the action of bacteriophage colonies were

obtained which not only gave the biochemical reactions of *Bact. pseudo-carolinus* but also showed serological relationship. We have recently been able to observe the reverse change. A strain of *Bact. pseudo-carolinus* isolated originally from a single-cell colony and maintained in culture for two years was lysed by bacteriophage. The secondary cultures obtained fermented glucose, mannite, and maltose with the production of acid only and were partially agglutinable with *flexneri* polyvalent serum. These changed fermentation reactions as well as the agglutinability have been maintained for six subcultures. This strain is still under investigation.

We have recorded these observations on the changes induced in *Bact. flexneri* and *Bact. pseudo-carolinus* under the influence of bacteriophage not only because they illustrate the profound changes induced in an organism under its influence, but also in view of the recent findings of Boyd (1936).

Boyd records that his no. 88 is numerically the most common of his 'new' types of dysentery bacilli in India. It differs biochemically from the V-Z races of *flexneri* in that about one-third of the strains isolated are late dulcitol fermenters. This organism, according to Boyd, shows a fairly close antigenic relationship to the V-Z 'spectrum', but is only feebly agglutinated by a V-Z polyvalent serum. It possesses a main antigen peculiar to itself.

According to Boyd this organism no. 88 presents certain features of great interest. Although differing in its biochemical relations no. 88 has been shown by Dr. W. M. Scott to be identical in its antigenic composition to the organism known in England as the Newcastle dysentery bacillus, which has been proved responsible for several small outbreaks of dysentery in England and elsewhere. Further, a strain having the biochemical characters of the Newcastle bacillus has been isolated from a case of dysentery in Bareilly. Boyd regards the discovery of the Newcastle dysentery bacillus in India as a matter of considerable importance, as it had hitherto been the practice in military laboratories to discard non-motile gas-forming organisms isolated from cases of dysentery. We have had in our collection for nearly two years one strain of Newcastle obtained from Kasauli. It gives the biochemical reactions of our *Bact. pseudo-carolinus*.

Although much work on the antigenic structure of these organisms remains to be done before their systematic position can be finally determined the facts recorded strongly suggest that the Newcastle bacillus is in reality *Bact. pseudo-carolinus*. We have already shown that a certain number of strains of *Bact. pseudo-carolinus* are late fermenters of dulcitol. This was not described by Castellani. Further, we have obtained from a strain of *Bact. pseudo-carolinus* variants which resemble Boyd's no. 88

and show antigenic relationship to the V-Z 'spectrum' of *flexneri*. The serological behaviour of the variant colonies obtained after the action of bacteriophage is further evidence of these bacilli belonging to a large group of organisms which possess a certain antigenic relationship and of which the only group that we know the antigenic structure is the V-Z group of *flexneri*. There are many anomalous findings which still have to be cleared up. Many of the strains are unstable, and show considerable variations both in their serological and biochemical properties. Evidence is gradually accumulating to show that many strains of intestinal bacilli isolated from time to time from cases of intestinal disturbances are variants of a group of antigenically related organisms. Various environmental factors, one of which is bacteriophage, play an important rôle in bringing about these changes and we are convinced from our own observations on the changes induced by bacteriophage in the test tube that no real progress in the study and rational classification of the dysentery bacilli will be made unless that study includes a careful consideration of all the environmental factors of which bacteriophage is one that we can easily control and study *in vitro*. Unfortunately much of the progress is retarded by the orthodox bacteriologist refusing to discard the now thread-bare belief in the fixity of species. We have shown that in the cholera vibrio profound changes can occur under the influence of bacteriophage. Similar changes occur in *Bact. flexneri* and *Bact. pseudo-carolinus*. We have observed changes in fermentative and serological properties and even in motility.

There is enough experimental proof to implicate *Bact. pseudo-carolinus* as a potential pathogen of the intestinal canal. Observations on this organism have been in progress for over nine years at the School of Tropical Medicine.

During 1934, we carried out a survey to determine the presence of agglutinins against this organism in a series of 250 hospital inpatients. The results of this survey are shown in the following table :—

TABLE

Showing the percentage of agglutinating sera obtained from 250 hospital in-patients at specified titre with a well-agglutinable strain of *Bact. pseudo-carolinus*

	1 to 25 and over	1 to 50 and over	1 to 100 and over	1 to 200 and over	1 to 400
Percentage of sera agglutin- able.	48	38	20	7	2

PITFALLS IN OPHTHALMIC PRACTICE

By C. R. CHAKRAVERTI, M.B.

House Surgeon, Eye Infirmary, Medical College Hospitals, Calcutta

BEFORE any discussion is taken up on the mistakes that are commonly met with in the everyday practice of ophthalmology, the first

(Continued from previous column)

It will be seen that a very large percentage of the 250 in-patients examined showed agglutinins for this organism. This at first sight appears to be a very high percentage particularly as only one strain was employed in the test but when it is remembered that from 7 per cent of these individuals we were able to recover *Bact. pseudo-carolinus* these results are not so extraordinary.

Summary

(1) The literature on *Bact. pseudo-carolinus* is reviewed.

(2) As this organism has not been fully described before, a description of *Bacterium pseudo-carolinus* is given. On the basis of Bergey's classification this organism belongs to the genus *Salmonella*; its exact position in that genus is not determined.

(3) Variant colonies were produced in a strain of *Bact. pseudo-carolinus* after the action of bacteriophage. These variants lost the property of producing gas in the fermentation of carbohydrates and showed antigenic relationship to *Bact. flexneri*.

(4) A suggestion is put forward that the so-called Newcastle dysentery bacillus and *Bact. pseudo-carolinus* are the same. Further, Boyd's dysentery bacillus no. 88 is similar to the anærogenous variant colonies of *Bact. pseudo-carolinus*.

(5) Evidence is recorded to show that *Bact. pseudo-carolinus*, one of the commonest non-lactose-fermenters, possesses pathogenic properties.

point that should be stressed is the fact that eye affections are, in the majority of cases, secondary, that is, they are either a localized manifestation of some general disease or an extension from the neighbouring structures.

The lid and conjunctiva.—A patient comes to a doctor complaining of trouble in his eyes. On examination the doctor finds the skin of the eye is excoriated, eczematous and the conjunctiva red and discharging. The diagnosis is chronic conjunctivitis with secondary blepharitis and immediately the doctor rushes on and prescribes the usual treatment for these local conditions. If he were only a little more careful in his examination, he would probably find that the patient was suffering from a generalized affection of the skin, for instance impetigo, furunculosis or ringworm, or some such affection of the scalp and forehead as seborrhœa or acne rosacea. In these cases the eye is either being showered with micro-organisms, or infection is carried to the eye by infected fingers. Unless the skin condition is attended to, the eye will fail to improve with treatment or may even actually get worse.

Another common cause of chronic conjunctivitis and blepharitis especially of the angular type is an infected tear sac. Until this is removed, for there is really no other alternative way of dealing with an infected sac, the conjunctival condition will evade all treatment. Chronic conjunctivitis causing a great deal of discomfort in the eye with very few objective signs can often be traced to a patient's occupation requiring exposure of the eyes to dust, glare and irritants over a prolonged period. Times without number such cases have been diagnosed as trachoma or granular lids. The patient is given various kinds of treatment consisting mostly of applications of caustics and irritant drugs. A pair of protective goggles, a mild salve or lotion and a few drops of liquid paraffin daily are all that are required to cure the trouble.

Granules and follicles.—Much confusion centres around these two terms. Granules or follicles are collections of lymphoid tissue in the sub-epithelial layer of the conjunctiva. The presence of these without any symptoms is of absolutely no significance and requires no treatment. Granulosis may be a localized manifestation of a general lymphoid hyperplasia and is physiologically present in young children in whom we also find a hyperplastic condition of similar tissues, namely spleen, thymus, tonsils and adenoids. The same condition is found in older children of a 'tuberculous diathesis'. Phlyctenulosis is a condition of the same group but with more serious ocular manifestations.

Spring catarrh or vernal conjunctivitis is due to constitutional causes of the same type. In the treatment of this disease attention should be paid to the constitutional causes. Plenty of

good food, sunshine, fresh air, the eradication of septic foci in the teeth or tonsils. The eye itself requires little or no treatment.

Trachoma is an exception to the above types of eye disease. The ætiology of the disease is still unknown but the consensus of opinion regards it as an infectious disease in which the infective organism, which has not yet been discovered, is supposed to lurk in the 'trachoma granules'. The presence of these granules has been the causation of the various kinds of destructive measures employed in the treatment of trachoma, namely, the eradication of granules by expression, cauterization or application of caustics such as copper sulphate and silver nitrate solutions. Nowadays, more attention is paid to the building up of the patient's own defences and destructive treatment has been discarded in favour of milder applications, namely, 0.5 per cent copper sulphate drops and weekly painting of the eyelids with 1 per cent to 2 per cent silver nitrate solution. This treatment should be carried out over a period of at least six months.

Copper sulphate stick has long been regarded as a specific in the treatment of trachoma. Nothing can be said too strongly to condemn this practice in India; copper sulphate destroys the raw and young corneal tissues and hence its use is absolutely contra-indicated in the presence of corneal ulcers which are frequently met with in the course of the disease.

One of the sequelæ of trachoma is entropion of the eyelids with trichiasis. A simple removal of the misdirected eyelashes is only a temporary measure for if the hair follicle is not destroyed the condition recurs in the course of a few weeks. The hair follicles can be very easily destroyed by the galvanic needle cautery and in the case of extensive trichiasis a Webster's mucous graft operation should be carried out. The latter is a very simple operation and the result is very satisfactory.

The use of pads and bandages in affections of the conjunctiva is very limited, especially in India. Whenever there is the least suspicion of a purulent discharge or any loss of epithelium in septic conditions, their use is contra-indicated, for a pent-up discharge aggravates the condition in the former case and in the latter case prolonged apposition of raw surfaces gives rise to symblepharon.

Before the discussion on the lids and conjunctiva is brought to a close, attention should be drawn to two other conditions, namely, acute inflammation and chronic blepharitis. In dealing with acute inflammation about the face and especially near the eye, the multiplicity of venous channels and the proximity of the cranial sinuses make any surgical interference an anxious process. Hence an extremely conservative attitude is usually necessary to allow the infection to localize in cases of acute styes,

infective chalazion, acute dacryocystitis and lid abscesses.

Blepharitis.—This disease is often treated for months without any benefit whatsoever. The infection lies at the root of the eyelashes. Small hard scales or crusts adhere very firmly to the eyelashes and surrounding skin and unless these crusts are softened with an alkaline lotion and then carefully removed with a swab stick no applications can get at the site of the micro-organisms. In all affections involving the lid margins or the conjunctiva, never forget to investigate the refraction of the eyes and to rectify any error found to be present.

Foreign body in the eye.—This is often a very deceptive ailment. A gritty sensation without any foreign body being present is felt when there is an ingrowing eyelash or loss of corneal epithelium. Corneal abrasions, epidemic superficial punctate keratitis, phlyctenular keratitis, dendritic ulcers or herpes of the cornea give rise to a gritty sensation on account of the irritation produced by every winking movement over the exposed nerve endings. A drop of 0.5 per cent alkaline fluorescein is all that is necessary to reveal the real nature of the complaint, as if there is a raw surface it stains bright green with this drug. In those cases in which the history is more definite, a careful search should be made in the fornices of the conjunctiva for the presence of a foreign body.

The removal of foreign bodies from the eye should always be done under a local anaesthetic and particular care should be taken in cases in which they have to be removed from the cornea, owing to the danger of a corneal opacity and, as a result, interference with vision. The abrasion left after removal of a foreign body from the cornea gives rise to a gritty sensation. This along with the presence of a corneal opacity gives the patient a false impression that the foreign body still remains. To obviate this, two important post-operative precautions should always be carried out :—

(1) Never throw away the foreign body until it has been shown to the patient and his friends who accompany him.

(2) Keep the eye firmly bandaged for some hours after the operation.

Ulcer serpens, also known as hypopyon ulcer.—In the treatment of this serious ulcer of the cornea two factors of vital importance are often lost sight of, namely, the cause and the intra-ocular tension of the affected eye. The commonest causes of hypopyon ulcer are an infected tear sac, purulent conjunctivitis and a retained foreign body. Unless the cause is removed, all treatment must necessarily be in vain. Deep inflammation of the cornea is attended as a rule with iridocyclitis and the nature of the aqueous humour changes at once to an exudation. This increased viscosity of the aqueous causes a rise of intra-ocular tension in most

cases and unless this tension is lowered by repeated paracentesis one cannot expect the ulcer to heal.

Cataract.—True cases of cataract demand no urgent treatment but a host of different eye diseases are labelled 'cataract'. To quote a few examples :—

(1) With advancing age the refractive index of the lens increases and more light is reflected back from its surface, thus giving the characteristic grey appearance which is seen in the pupils of old people. Unfortunately these cases are often diagnosed as cataract; this causes unnecessary anxiety to the patient as the lens may be absolutely normal.

(2) The patient is suffering from chronic simple glaucoma which is slowly and insidiously leading towards irrecoverable blindness from optic atrophy. The family doctor after a cursory examination of the eyes assures the patient that he is getting cataract as his vision is slowly getting worse. He tells his patient that it is too early to do anything to improve the sight and the operation for the cure of cataract is not advised as long as any vision is left. Later, when the real cause of the loss of vision is discovered by an oculist, it is too late to do anything, for the patient is blind for ever, the result of glaucoma and not of cataract.

(3) A young child with a grey pupil is brought for treatment and the doctor diagnoses his case as one of cataract. Treatment is deferred. A few months later the same child is seen with a huge glioma (retinoblastoma) covering half his face and eating into his brain, presenting a most dreadful sight which the unfortunate parents have to endure until death supervenes. It is 'criminal' to diagnose cataract without a proper examination of the eyes, in the dark room.

With regard to the treatment of cataract, two points should be carefully observed :—

(1) The congenital and infantile varieties of cataract should be operated upon as early as possible in the child's life, otherwise there is the risk of amblyopia ex anopsia developing.

(2) Immature senile cataract. The conservative method is to wait until the cataract is mature but the word maturity is fast losing its previous significance. Nowadays, when useful vision is lost expert ophthalmic surgeons frequently remove immature lenses by intra-capsular methods, without leaving any after-cataract; in the hands of experts the operation gives the most perfect results.

Glaucoma.—Acute glaucoma is a condition of surgical emergency and no time should be lost in carrying out treatment. The commonest type of glaucoma seen in India is the chronic simple primary type. It is a very insidious disease and its diagnosis is often one of extreme difficulty. There are three cardinal signs, increased intra-ocular tension, depression of the visual

point that should be stressed is the fact that eye affections are, in the majority of cases, secondary, that is, they are either a localized manifestation of some general disease or an extension from the neighbouring structures.

The lid and conjunctiva.—A patient comes to a doctor complaining of trouble in his eyes. On examination the doctor finds the skin of the eye is excoriated, eczematous and the conjunctiva red and discharging. The diagnosis is chronic conjunctivitis with secondary blepharitis and immediately the doctor rushes on and prescribes the usual treatment for these local conditions. If he were only a little more careful in his examination, he would probably find that the patient was suffering from a generalized affection of the skin, for instance impetigo, furunculosis or ringworm, or some such affection of the scalp and forehead as seborrhœa or acne rosacea. In these cases the eye is either being showered with micro-organisms, or infection is carried to the eye by infected fingers. Unless the skin condition is attended to, the eye will fail to improve with treatment or may even actually get worse.

Another common cause of chronic conjunctivitis and blepharitis especially of the angular type is an infected tear sac. Until this is removed, for there is really no other alternative way of dealing with an infected sac, the conjunctival condition will evade all treatment. Chronic conjunctivitis causing a great deal of discomfort in the eye with very few objective signs can often be traced to a patient's occupation requiring exposure of the eyes to dust, glare and irritants over a prolonged period. Times without number such cases have been diagnosed as trachoma or granular lids. The patient is given various kinds of treatment consisting mostly of applications of caustics and irritant drugs. A pair of protective goggles, a mild salve or lotion and a few drops of liquid paraffin daily are all that are required to cure the trouble.

Granules and follicles.—Much confusion centres around these two terms. Granules or follicles are collections of lymphoid tissue in the sub-epithelial layer of the conjunctiva. The presence of these without any symptoms is of absolutely no significance and requires no treatment. 'Granulosis' may be a localized manifestation of a general lymphoid hyperplasia and is physiologically present in young children in whom we also find a hyperplastic condition of similar tissues, namely spleen, thymus, tonsils and adenoids. The same condition is found in older children of a 'tuberculous diathesis'. Phlyctenulosis is a condition of the same group but with more serious ocular manifestations.

Spring catarrh or vernal conjunctivitis is due to constitutional causes of the same type. In the treatment of this disease attention should be paid to the constitutional causes. Plenty of

good food, sunshine, fresh air, the eradication of septic foci in the teeth or tonsils. The eye itself requires little or no treatment.

Trachoma is an exception to the above types of eye disease. The ætiology of the disease is still unknown but the consensus of opinion regards it as an infectious disease in which the infective organism, which has not yet been discovered, is supposed to lurk in the 'trachoma granules'. The presence of these granules has been the causation of the various kinds of destructive measures employed in the treatment of trachoma, namely, the eradication of granules by expression, cauterization or application of caustics such as copper sulphate and silver nitrate solutions. Nowadays, more attention is paid to the building up of the patient's own defences and destructive treatment has been discarded in favour of milder applications, namely, 0.5 per cent copper sulphate drops and weekly painting of the eyelids with 1 per cent to 2 per cent silver nitrate solution. This treatment should be carried out over a period of at least six months.

Copper sulphate stick has long been regarded as a specific in the treatment of trachoma. Nothing can be said too strongly to condemn this practice in India; copper sulphate destroys the raw and young corneal tissues and hence its use is absolutely contra-indicated in the presence of corneal ulcers which are frequently met with in the course of the disease.

One of the sequelæ of trachoma is entropion of the eyelids with trichiasis. A simple removal of the misdirected eyelashes is only a temporary measure for if the hair follicle is not destroyed the condition recurs in the course of a few weeks. The hair follicles can be very easily destroyed by the galvanic needle cautery and in the case of extensive trichiasis a Webster's mucous graft operation should be carried out. The latter is a very simple operation and the result is very satisfactory.

The use of pads and bandages in affections of the conjunctiva is very limited, especially in India. Whenever there is the least suspicion of a purulent discharge or any loss of epithelium in septic conditions, their use is contra-indicated, for a pent-up discharge aggravates the condition in the former case and in the latter case prolonged apposition of raw surfaces gives rise to symblepharon.

Before the discussion on the lids and conjunctiva is brought to a close, attention should be drawn to two other conditions, namely, acute inflammation and chronic blepharitis. In dealing with acute inflammation about the face and especially near the eye, the multiplicity of venous channels and the proximity of the cranial sinuses make any surgical interference an anxious process. Hence an extremely conservative attitude is usually necessary to allow the infection to localize in cases of acute styes,

infective chalazion, acute dacryocystitis and lid abscesses.

Blepharitis.—This disease is often treated for months without any benefit whatsoever. The infection lies at the root of the eyelashes. Small hard scales or crusts adhere very firmly to the eyelashes and surrounding skin and unless these crusts are softened with an alkaline lotion and then carefully removed with a swab stick no applications can get at the site of the micro-organisms. In all affections involving the lid margins or the conjunctiva, never forget to investigate the refraction of the eyes and to rectify any error found to be present.

Foreign body in the eye.—This is often a very deceptive ailment. A gritty sensation without any foreign body being present is felt when there is an ingrowing eyelash or loss of corneal epithelium. Corneal abrasions, epidemic superficial punctate keratitis, phlyctenular keratitis, dendritic ulcers or herpes of the cornea give rise to a gritty sensation on account of the irritation produced by every winking movement over the exposed nerve endings. A drop of 0.5 per cent alkaline fluorescein is all that is necessary to reveal the real nature of the complaint, as if there is a raw surface it stains bright green with this drug. In those cases in which the history is more definite, a careful search should be made in the fornices of the conjunctiva for the presence of a foreign body.

The removal of foreign bodies from the eye should always be done under a local anæsthetic and particular care should be taken in cases in which they have to be removed from the cornea, owing to the danger of a corneal opacity and, as a result, interference with vision. The abrasion left after removal of a foreign body from the cornea gives rise to a gritty sensation. This along with the presence of a corneal opacity gives the patient a false impression that the foreign body still remains. To obviate this, two important post-operative precautions should always be carried out :—

(1) Never throw away the foreign body until it has been shown to the patient and his friends who accompany him.

(2) Keep the eye firmly bandaged for some hours after the operation.

Ulcer serpens, also known as hypopyon ulcer.—In the treatment of this serious ulcer of the cornea two factors of vital importance are often lost sight of, namely, the cause and the intra-ocular tension of the affected eye. The commonest causes of hypopyon ulcer are an infected tear sac, purulent conjunctivitis and a retained foreign body. Unless the cause is removed, all treatment must necessarily be in vain. Deep inflammation of the cornea is attended as a rule with iridocyclitis and the nature of the aqueous humour changes at once to an exudation. This increased viscosity of the aqueous causes a rise of intra-ocular tension in most

cases and unless this tension is lowered by repeated paracentesis one cannot expect the ulcer to heal.

Cataract.—True cases of cataract demand no urgent treatment but a host of different eye diseases are labelled 'cataract'. To quote a few examples :—

(1) With advancing age the refractive index of the lens increases and more light is reflected back from its surface, thus giving the characteristic grey appearance which is seen in the pupils of old people. Unfortunately these cases are often diagnosed as cataract; this causes unnecessary anxiety to the patient as the lens may be absolutely normal.

(2) The patient is suffering from chronic simple glaucoma which is slowly and insidiously leading towards irrecoverable blindness from optic atrophy. The family doctor after a cursory examination of the eyes assures the patient that he is getting cataract as his vision is slowly getting worse. He tells his patient that it is too early to do anything to improve the sight and the operation for the cure of cataract is not advised as long as any vision is left. Later, when the real cause of the loss of vision is discovered by an oculist, it is too late to do anything, for the patient is blind for ever, the result of glaucoma and not of cataract.

(3) A young child with a grey pupil is brought for treatment and the doctor diagnoses his case as one of cataract. Treatment is deferred. A few months later the same child is seen with a huge glioma (retinoblastoma) covering half his face and eating into his brain, presenting a most dreadful sight which the unfortunate parents have to endure until death supervenes. It is 'criminal' to diagnose cataract without a proper examination of the eyes, in the dark room.

With regard to the treatment of cataract, two points should be carefully observed :—

(1) The congenital and infantile varieties of cataract should be operated upon as early as possible in the child's life, otherwise there is the risk of amblyopia ex anopsia developing.

(2) Immature senile cataract. The conservative method is to wait until the cataract is mature but the word maturity is fast losing its previous significance. Nowadays, when useful vision is lost expert ophthalmic surgeons frequently remove immature lenses by intra-capsular methods, without leaving any after-cataract; in the hands of experts the operation gives the most perfect results.

Glaucoma.—Acute glaucoma is a condition of surgical emergency and no time should be lost in carrying out treatment. The commonest type of glaucoma seen in India is the chronic simple primary type. It is a very insidious disease and its diagnosis is often one of extreme difficulty. There are three cardinal signs, increased intra-ocular tension, depression of the visual

fields and the presence of glaucomatous cupping. The measurement of tension requires a special instrument which is costly, extremely delicate, very easily gets out of order and requires expert handling. The fundi of the eyes show pathological changes in the way of glaucomatous cupping only when the disease is far advanced and even then it usually requires an expert to diagnose the changes in the optic discs.

The easiest method of making an early diagnosis of glaucoma is by mapping out the fields of vision. As the disease advances the fields show a progressive depression commencing first in one or both nasal quadrants, and the vertical depression of the blind spot. The central vision usually remains unaffected until the disease is very far advanced. The treatment for this type of glaucoma is always surgical and the best of the many operations for this disease in India is Elliot's sclero-corneal trephining.

One special variety of chronic simple glaucoma is common in Bengal and in the last year has occurred amongst Bengalis in the United Provinces, Bihar and Burma and is a symptom of epidemic dropsy. Epidemic dropsy is very commonly called *beri-beri* by the public but is an entirely different disease; it is due to a toxic cause and is not an avitaminosis. This epidemic dropsy gives rise to a temporary glaucoma without any signs of inflammation and, provided the fields of vision are normal, general treatment is all that is required; this consists of a complete stopping of rice as an article of diet, the administration of drugs such as ephedrine and if possible complete change of climate from the endemic area. The bowels should also be kept freely open. Local applications such as myotics to reduce tension are absolutely useless and should not be prescribed. Eserine is an irritant and sets up an inflammation and so makes operation more difficult should this be required later.

Strabismus or squint.—The general practitioner's knowledge of the causes of this condition is very meagre and this is the explanation why so few cases among Indians come to eye hospitals for early treatment. The following points should be borne in mind :—

(1) Concomitant convergent strabismus is the commonest variety of the condition.

(2) Unless the squinting eye is treated very early it becomes amblyopic, that is an eye with permanent partial sight.

(3) Errors of refraction are a common cause of the condition. If the eyes are examined under atropine as soon as the deformity is observed and the error of refraction fully corrected by glasses, the squint in most cases will be cured without operation.

(4) There is very little hope of regaining normal vision for a squinting eye if treatment is commenced when the child is older than six years. The affected eye can always be put

straight by a simple operation in the hands of an expert.

Dark-room examination.—This consists of the examination of the eye by oblique illumination and with the ophthalmoscope. The corneal loupe and the condensing lens are used for the detection of small opacities, ulcers, foreign bodies and keratitis precipitates of the cornea, also for minute changes in the iris and the lens. If a slit lamp and corneal microscope are available more minute changes in the cornea, iris, anterior chamber and lens can be detected. To examine the media, the pupils should be dilated with homatropine and the plane mirror of the ophthalmoscope should be used. Minute opacities in the media are usually seen by this method. If these opacities change their position when the eye is moved they must either be in the aqueous or in the vitreous; if stationary, they must be in the lens. By this method dislocation of the lens and retinal detachment can also be easily diagnosed. The ophthalmoscope is necessary to diagnose diseases of the retina and choroid.

Direct ophthalmoscopy.—To carry out this examination efficiently a mydriatic is required. The following points are worth observing when conducting this examination :—

(1) Direct ophthalmoscopy should never be carried out before first examining the eye by oblique illumination and with the plane mirror. This prevents unnecessary waste of time as it gives a bird's-eye view of the whole eye, as, if the media are not clear, it is useless to carry out direct ophthalmoscopy.

(2) The highest convex lens should always be in the sight hole to start with and the strength of the lens should be slowly wheeled down until the fundus is in focus. In this way all the structures from the cornea down to the fundus in turn come into focus and this prevents any structure from being overlooked. It has the further advantage of giving one an idea as to the depth of the object in focus and is extremely useful in the detection of retinal detachment, changes in the vitreous, intra-ocular tumours, papilloedema, glaucomatous cupping, etc. It also gives a fair idea of the refractive index of the eye.

(3) The ophthalmoscope should be brought as close to the eye of the patient as possible. Frequently cases are seen in which the media appeared to be clear but the fundus could not be seen. These are usually cases of high myopia and in inexperienced hands the fundi are better examined by indirect ophthalmoscopy.

(4) Examination of the periphery of the fundus should never be omitted as very often the earliest evidence of disease lies there, namely, retinitis pigmentosa, retinal detachment, etc. It is a good plan to examine the optic disc first of all, then the macula and lastly the periphery.

A-O TUBERCULIN IN OPHTHALMOLOGY

By B. P. BANAJI, F.R.C.S.I.

Bombay

TUBERCULIN therapy has come to stay in ophthalmological practice though general surgeons, as far as I am aware, are not at all enthusiastic about its therapeutic value in local surgical tuberculosis.

(Continued from previous page)

Refraction.—The work of refraction is intimately connected with mydriatics and retinoscopy. Without these, only simple presbyopic glasses should be prescribed. Up to the age of 16 years the best mydriatic is atropine and preferably should be prescribed as an ointment. For older patients homatropine is sufficient. Atropine should never be prescribed for patients over forty years of age because of the risk of glaucoma. Retinoscopy is very essential in cases of astigmatism and one should think twice before prescribing astigmatic glasses with the axis asymmetric. No age is too young to have glasses if there is an error of refraction. Young children and illiterate people who do not know the alphabet can have correct glasses prescribed with the help of an 'E' chart and retinoscopy by a refractionist.

Conclusion.—Success in the practice of ophthalmology is to a large extent a matter of careful attention to detail. Before operations, examination of the urine for albumin and sugar, the eradication of focal sepsis, and proper sterilization of the field are essential. In cases of operation on the eyeball, proper anaesthesia (conjunctival and retrobulbar ciliary blocking) and fascial akinesia guard against serious complications like escape of vitreous, etc. A small peripheral button-hole iridectomy (except in cases of patients with one eye where complete iridectomy is indicated) prevents prolapse of the iris after cataract operations. Careful examination of the pupil reactions, the determination of perception and projection of light and colour vision save the surgeon from operating in cases of cataract in which optic atrophy is present, and in which no vision can be restored.

The eye is a delicate organ and as such it should be handled with extreme gentleness and care. The mildest medicines, namely, normal saline lotion and boric lotions, liquid paraffin drops and boro-vaseline should as far as possible only be prescribed.

I am indebted to Lieut.-Col. E. W. O'G. Kirwan, Professor of Ophthalmology, Medical College, Calcutta, for his teaching, encouragement and for the inspiration he has given me to write this article.

The old tuberculin of Koch, long given up by physicians and general surgeons, has even now its advocates amongst ophthalmic surgeons though the introduction of Prof. Arima's A-O tuberculin ought to induce ophthalmologists to give up that dangerous therapeutic agent.

The A-O tuberculin appears to be the outcome of a most laborious search for a strain of tubercle bacillus which contains within its body more antibody-producing substances than tissue-destroying elements.

In 1931, I saw A-O tuberculin, a product of Japan, used both in Berlin and Vienna, the home of bacterial vaccines and that too in spite of its heavy cost. Since then I have used it in my practice, in some cases with remarkable results. I have no experience of its prophylactic use, but it is said that it could be administered to newborn babies without any harm.

Diagnostic value.—A-O tuberculin is also used for purpose of diagnosis. A blood smear for a leucocytic count is prepared and then 1 c.cm. of A-O tuberculin is injected.

Four more smears are made every half hour, half an hour after the injection of tuberculin. A leucocytic count is then made from all the five smears and a comparative chart is drawn with reference to the leucocytes in the original pre-injection collection.

In cases with a strongly positive reaction, there is a decrease of leucocytes (about 3,000) immediately after the injection and in the last collection the number has not returned to the original. In normal individuals there is very slight or no decrease in the number of leucocytes immediately after the injection; it tends rapidly to become normal or shows a tendency to increase.

As regards its administration for treatment, one ampoule of 1 c.cm. is given to adults once a week for twenty consecutive weeks. I have used it for the following tuberculous conditions:

Phlyctens, iritis, keratitis, recurrent retinal hæmorrhages in the young, choroiditis, and necrosis of the orbit.

I am not impressed with its value in recurrent phlyctens, specially those accompanied by severe blepharospasm. Most probably the ætiology of these cases comprises something more than tuberculous allergy. I strongly recommend its use in keratitis, iritis and hæmorrhages of the young. Of all the successful cases the most remarkable was that of a brother of a doctor who was suffering from relapsing keratitis, which had produced dense opacity of the cornea of one eye and an early affection of the other. In spite of all known treatment including new tuberculin (B. E.) the case was going from bad to worse. The use of A-O tuberculin ultimately cured the second eye and for the last year there has been no indication of a relapse.

RESPONSE TO PILOCARPINE IN CASES OF ASTHMA

By DHARMENDRA, M.B., B.S.

School of Tropical Medicine, Calcutta

PILOCARPINE stimulates the vagus nerve endings, the secretory nerves, and the nerve endings governing the involuntary muscles. Its action is thus directly antagonistic to atropine. By stimulating the vagal nerve endings in the bronchi it increases the bronchiolar contraction and the breathing may become laboured. By stimulating the secretory nerve endings it produces a copious secretion of saliva, flushing of the face and neck followed by profuse sweating, and running from the eyes and the nose. By stimulating the nerve endings governing the involuntary muscles it causes increased peristaltic movements of the unstriated muscles of the gastro-intestinal tract and may cause nausea, vomiting, colicky pains and diarrhoea.

The pharmacopoeial dose of pilocarpine nitrate is gr. 1/5 to 1/20; generally a dose of gr. 1/6 is used and in this dose it produces the reactions in a normal individual. Alexander and Padlock (1921) have observed that in doses of 1/20 gr. it produces very scant or no response in normal individuals whereas the same dose elicits varying degrees of reaction in vagotonic individuals. Using this dose they found an abnormally increased sensitiveness to pilocarpine amongst asthmatics.

We tested the pilocarpine response in 47 cases of asthma and in 11 non-asthmatics who served as control. In the case of asthmatics the test was done during an interval of freedom from the attacks. A hypodermic injection of gr. 1/20 of pilocarpine nitrate was used and the symptoms looked for after the injection included increased salivation, increased perspiration, flushing of the face, a feeling of warmth and running from the eyes and nose, etc.

Amongst the 11 controls none showed any marked reaction, 2 reacted slightly with increased salivation, and a feeling of warmth, 8 reacted very slightly with increased salivation and there was no reaction in one case.

Amongst the 47 asthmatics there was marked reaction in 30 cases, slight reaction in 12 cases and no reaction in 5 cases (table I). In the

TABLE I

Type of cases	Number of cases	RESPONSE TO GR. 1/20 OF PILOCARPINE NITRATE		
		Marked	Slight	Very slight or negative
Asthma	47	30	12	5
Control	11	..	2	9

30 cases reacting markedly the response consisted in a great increase in salivation and

perspiration, flushing of the face and a feeling of warmth. In addition there was some shaking and trembling of the limbs in 4 cases, slight running from the nose in 2 cases, headache and vomiting in one case, headache in 2 cases, palpitation of the heart in one case, and one patient complained of feeling sleepy. In three of the cases the test was followed by increased cough and one patient had an attack during the following night. Increased perspiration and salivation began in about 10 minutes and lasted for about half an hour or longer; the other symptoms lasted for a much shorter period. In the cases reacting only slightly, there was slight salivation or slight perspiration or both, and the symptoms lasted for about 10 minutes or so.

Amongst the 47 cases of asthma, the symptoms in 36 cases were dependent on some pathological change in the respiratory tract (bronchial cases) and the remaining 11 were of the allergic type.

An analysis of the pilocarpine test according to this grouping is shown in table II. It will

TABLE II

Type of cases	Number of cases	RESPONSE TO PILOCARPINE		
		Marked	Slight	Negative
Bronchial	36	28	8	..
Allergic ..	11	2	4	5
TOTAL ..	47	30	12	5

be seen that out of the 36 bronchial cases there was marked reaction in 28 and slight reaction in 8 cases. Amongst the 11 allergic cases the reaction was marked in 2, slight in 4, and negative in 5 cases. This shows that the bronchial cases are extremely sensitive to pilocarpine while the allergic ones are comparatively less so. In other words there is marked vagotonia in the bronchial cases while the allergic ones are not necessarily vagotonic.

I will refer here to another clinical observation. In the patients reacting markedly to the pilocarpine test the attack was relieved by a hypodermic injection of gr. 1/150 of atropine sulphate and the relief was usually more marked than by an injection of adrenaline. (Atropine acts by paralysing the vagal nerve endings.) In the patients reacting only slightly to the pilocarpine test the attacks were relieved by an injection of 0.5 c.c. of a 1 in 1,000 solution of adrenaline chloride and the atropine injection had only slight or no effect at all. In 6 of the 47 cases we had an opportunity of studying the effects of both atropine and adrenaline on the asthmatic attacks.

The pilocarpine response and the therapeutic effects of atropine and adrenaline in these cases

TABLE III

Serial number	Type of cases	RESPONSE TO GR. 1/20 PILOCARPINE NITRATE				EFFECT ON THE ATTACK	
		Flushing	Sweating	Salivation	Other symptoms	Hypodermic injection of 0.5 c.c. adrenaline chloride	Hypodermic injection gr. 1/150 atropine sulphate
1	Bronchial	+	+	+	Trembling	Not relieved	Relieved.
2	Bronchial	++	++	++	Feeling sleepy	Relieved	Relieved.
3	Mixed	—	—	Slight	Slight running from nose.	Relieved	Relieved.
4	Bronchial	—	+	—	Headache	Relieved	Partial relief.
5	Bronchial	+	++	++	Asthmatic attack during the following night.	Partial relief	Relieved.
6	Allergic	—	—	+	Relieved	Not relieved.

are shown in table III. It will be seen that the pilocarpine response was marked in three cases and only slight in the other three. Asthmatic attacks in all the 3 cases reacting markedly to pilocarpine were relieved by atropine injection, while adrenaline gave relief in one case, only partial relief in the second and no relief in the third case. On the other hand the attacks in all 3 cases reacting only slightly to pilocarpine were relieved by adrenaline while atropine gave relief in only one of these cases, partial relief in the second and no relief in the third case.

Summary

(1) The response to an injection of gr. 1/20 pilocarpine nitrate was tested in 47 asthmatics and 11 non-asthmatics.

(2) Amongst the asthmatics, there was marked reaction in 30 cases, slight reaction in 12 cases, and no reaction in 5 cases. Amongst the controls, 2 reacted slightly and 9 very slightly or not at all. This shows an increased susceptibility to pilocarpine in asthmatics.

(3) This increased susceptibility to pilocarpine is more marked in cases of asthma dependent on some pathological condition in the respiratory tract, i.e., bronchial cases, than in the allergic cases.

(4) The attacks in the cases reacting markedly to pilocarpine are relieved by a hypodermic injection of gr. 1/150 of atropine sulphate. In the cases reacting only slightly to pilocarpine the attacks are relieved by an injection of adrenaline.

For permission to publish this note, my thanks are due to Dr. L. Everard Napier, under whose charge the patients referred to were being treated and in whose department I am working.

THE SO-CALLED MYSTERY DISEASE OF CALCUTTA (*JHIN-JHINIA* OR *THAR-THARIA*)

By R. N. CHOPRA, C.I.E., K.H.P., M.A., M.D. (Cantab.)
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

and

R. N. CHAUDHURI, M.B. (Cal.)
(School of Tropical Medicine, Calcutta)

WHEN the epidemic of epidemic dropsy was over last year, there broke out the so-called 'mystery disease' in the vicinity of Calcutta. It was first reported in a Bengali daily paper and subsequently the District Health Officer of 24-Parganas came and saw us and reported that this unknown disease had been prevalent in Hashnabad thana in Basirhat subdivision about 40 miles from Calcutta. He had not seen any case himself, but he gave a description of what he had heard and asked for instructions in the matter. About the middle of November 1935, a field party was sent by the senior author to this place to carry out a preliminary investigation.

Information collected showed that the 'disease' started suddenly in the latter part of September 1935 at Bolbule and Katakhal villages on the right bank of the Ichamati river. Next the other villages were said to be affected, one after another along this river and it was foretold at that time that it would soon reach Calcutta. When a village was affected, a number of villagers were said to fall victims to it. The average duration of the 'disease' in one particular village was about a week after which only stray cases might be found. The 'disease' usually attacked persons in the evening after 4 p.m. though there were some cases with morning attacks. It was said that about 40 to 50 inhabitants of a village were attacked in one night. It was first confined mostly to the Mohammedan females but later the male sex and the Hindus were also affected. The majority were between the ages of 18 and 35 years,

though it was said that a child of 3 years and a man of 60 years suffered from it. The majority had only one attack; these were a few who were said to have had more than one attack. Enquiries from 20 affected villages showed that there was no authenticated case of death due to this condition.

The 'disease' is said usually to start suddenly with a tingling sensation in one or both feet, especially the big toes. The sensation then spreads up along the body to the head. Many patients are said to complain also of headache, giddiness and hot burning sensation in the head. Simultaneously with or soon after this subjective sensation, the victim begins to shiver and may have severe movements of the whole body. The eyes are said to be intensely congested and the body stiff during an attack. Symptoms vary in severity; they may be mild or severe; consciousness is as a rule retained. The attack lasts from a few minutes to a few hours. According to the belief commonly held by the villagers, this 'disease' causes the blood to rush from the feet up to the head. The diminished blood in the feet causes the initial tingling and the excessive blood in the head gives rise to hot burning sensation, dizziness, muscular movements and congestion of eyes. They call it *jhin-jhinia* because of this tingling sensation and *thartharia* because of the shivering.

Their method of treatment is based on this view and is somewhat inhuman. The patient is not allowed to lie down, as further rush of blood to the brain may be fatal! He is therefore tied to a post or tree or held up in an erect posture. Cold water is poured on the head continuously so that the blood may go back to the legs, congestion of the brain be relieved and the life may thereby be saved! This practice is carried on for hours together or till the patient feels too cold and asks for it to be stopped. Sometimes several hundred pitcherfuls or bucketfuls of water are poured on the head, and this procedure in this cold season must not only be very trying but a source of danger. This method, it is said, was first started by a village school master, when one of his students fainted in the school and this novel practice has since then been widely adopted. At times water is poured as soon as any tingling is complained of just to avert the attack. Tying the big toe with thread is said to have been an effective prophylactic measure in many cases! Cauliflowers and brinjals have often been incriminated as causative factors and many have stopped eating them through fear.

At Hashnabad and near by about nine cases only were seen of which seven were examined after their attacks were over and two while the attack was in progress, in fact when water was being poured on them.

Case I.—Patient, K. P.'s wife, Hindu, female, aged 18 years. In the evening of 14th November, 1935, she felt giddy, palpitation and tingling about the toes and

heels; this was followed by the 'shaking' of the whole body. Water was poured on her from 7 to 10 p.m. when she had a very severe rigor and was taken to bed. She could not sleep the whole night and her eyes were congested. She had also milder attacks on the following two evenings.

Physical examination done on 17th November, 1935, revealed no abnormality except slight pallor and increased knee-jerks. Her pulse was 70 and respiration 20 per minute. Blood pressure was 120/80 mm. of Hg. There was a history of hysterical fits for some years.

Case II.—Patient, R. B., Mohammedan, male, aged 26 years. On 13th November, 1935, at about 6 p.m. he felt a tingling sensation about the right shin bone followed by vertigo and a hot sensation in the head. Then there was the 'shaking' of the whole body till 10 p.m. His eyes turned red. He was relieved by sweet drinks and pouring of water.

Physical examination on 17th November, 1935, showed no abnormality except increased knee-jerks and a palpable spleen. Pulse was 74 and respiration 24 per minute. Blood pressure was 118/86 mm. mercury.

Case III.—Patient, J. A. S.'s wife, Mohammedan female, aged 20 years. On 15th November, 1935, at 1 a.m. she had a cramp in the right leg for about 10 minutes. Then she became very stiff but had no shivering. Water was poured on her and she recovered soon after it. On the 16th evening she complained of dryness of throat and groaned for a while, but the attack passed off itself. On the 17th morning she complained of tingling in the legs passing up to the head. Her eyes turned red and she was said to be 'unconscious' for some time. Recovery followed the usual treatment of pouring cold water on the head.

Physical examination done on 17th November, 1935, revealed no abnormality except enlargement of the spleen down to the umbilicus. Pulse was 76 and respiration 22 per minute. Blood pressure was 108/75 mm. of Hg. Knee-jerks were normal.

Case IV.—Patient, T. B.'s wife, Hindu, female, aged 32 years. On 15th November, 1935, while carrying a pitcherful of water she felt as if her left foot was cracked and her body started shaking. She went to the next house, where the people poured water on her and controlled the attack. She was conscious all the time and her eyes did not turn red. Same night she had another attack, which was again cured by pouring water.

She suffers from chronic cough and gave a history of hæmoptysis. Physical examination showed enlargement of the liver and crepitations at the apex of the left lung.

Case V.—Patient, late A. B.'s wife, Hindu, female, aged 35 years. On 16th November, 1935, while washing utensils in a tank she suddenly got tingling sensation in the right leg, which gradually spread up to the right shoulder and back of the neck. This was followed by throbbing sensation in the head and a feeling of constriction about the heart. Then her body started shaking. She was said to be quite conscious, but could not speak. The attack was controlled by water treatment.

There was history of hysterical fits in this patient. No abnormality was detected on physical examination. Pulse was 64 and respiration 24 p.m. Blood pressure was 134/84 mm. of Hg.

Case VI.—Patient, M. S.'s wife, Mohammedan, female, aged 30 years. On the 14th and 15th November, she had high fever with rigor. On the 16th in the evening she felt giddy and a tingling sensation in the left leg which was followed by shaking of the whole body. Water was poured on her for about an hour when she recovered.

Physical examination—Patient looked weak and ill. Eyes were normal. Heart sounds were weak. Pulse was 92 and respiration 28 per minute. Blood pressure was 120/85 mm. of Hg.

Case VII.—B., Hindu, female, aged 12 years. On the 17th afternoon she complained of pain in the orbits and felt as if her head was bursting. She complained

of tingling of the feet, had a rigor and vomited twice. Water was poured on her for about three-quarters of an hour, when our party arrived. She was conscious. There was no congestion of the eyes. 'Shaking' of the body was a mere shivering due to cold. Her clothes were changed and she was put to bed with quilts on in spite of the protest by her people that she would be worse or even die if laid down. Nothing untoward happened, rather the patient felt better.

Physical examination showed enlargement of the spleen 1½ inches below the costal margin. Other systems were normal. Temperature was subnormal, pulse 104 and respiration 30 per minute. Blood pressure was 106/70 mm. of Hg. (malignant tertian malarial parasite rings were found in the blood).

Case VIII.—Patient, M. A., Mohammedan, female, aged 30 years. There was the usual history of tingling followed by trembling. She was seen while water was being poured on her at about 8 p.m. She was shivering with cold, the field party stopped it, put her to bed and she felt comfortable. Her spleen was enlarged. No other abnormality was detected.

Case IX.—A Mohammedan, female, aged 18 years. She gave a history of a mild attack on 15th November, 1935. She stated that she had an attack of palpitation and tingling of the feet, but quick administration of water on the head aborted the attack! Excepting slight tachycardia nothing abnormal was detected.

Later, intimation was brought from the Director of Public Health that cases were reported from Khulna and Jessore also and that there were no deaths. The District Health Officer, Alipur, wrote on the 4th December, 1935, reporting an outbreak in a virulent form in Barasat and its vicinity. The place was visited by the field party on the 8th December, but hardly any case could be seen. According to the version of the subdivisional officer, the officer in charge of the thana and the sub-assistant surgeon in charge of the dispensary, there were only two cases in Barasat—one in the court and another in the 'hat'.

Case X.—In an adjacent village, Hridaypur, a boy, Hindu, male, aged 20 years, was examined. He had an attack a few days ago and his father stated that there was a good deal of discussion about the 'disease' in his house following the case occurring in the 'hat'. At about 10 p.m. he complained of hot sensation inside the head and could not move, but he was quite conscious; water was poured on him and within ten minutes he was all right. Physical examination showed diminished knee-jerks and palpable spleen.

Panicky topics were being extensively discussed in public places like the court, 'hat', etc. The field party was informed that in some places towards Basirhat, the villagers have been warned by the beating of drums not to go alone especially after sunset or at least three persons should go together and carry a pitcher with them for safety sake.

Case XI.—Hindu, boy of a respectable family, aged 14 years, was brought from Basirhat to the School of Tropical Medicine for examination. He had an attack in his school and was cured by water treatment. No abnormality was detected in him. We were subsequently informed that he had another attack of a mild type afterwards.

As prophesied, subsequently a number of cases occurred in Calcutta and six cases were admitted into the Carmichael Hospital for Tropical Diseases.

Case XII.—S. H., a Hindu, male, aged about 35 years, a mechanic, came from his village 'Gore', about nine miles from Sealdah to the workshop in Calcutta

on 20th December, 1935. After working for 10 minutes he felt a severe tingling sensation in the right toe followed by aching of the whole of the right leg. This lasted for about three minutes when he started shivering. There was a 'shaking' of the whole body for about 2 minutes. Next, he felt as if his whole body was paralysed and he could not move. It was said that at this time he lost consciousness, his eyes turned very red and his body was very hot to the touch. He was held up by two men and water was poured on his head by buckets. After about 12 buckets of water were poured on his head he became conscious and felt very chilly. Subsequently more water (altogether about 30 buckets) was poured and ice applied on the head and nape of neck. He was then brought to the Carmichael Hospital for Tropical Diseases.

He stated that his niece, a girl of 18 years, had an attack the night before last (18th December, 1935). There was no other case in the same village. He had also heard of a death in an adjacent village about a week ago; it was rumoured that the victim's eyes burst leading to hæmorrhage and death! In another case, he heard that the skull of a man exploded during an attack while he was working in the field!

Physical examination.—Decubitus—patient lying down having rigor—fully conscious. Eyes slightly congested. Pupils equal, normal size, reacting to light and accommodation. Vision clear. Ears—hearing normal. Nose—sensation of smell unaffected. Tonsils enlarged. Teeth and gums—pyorrhœa present. Tongue clean and moist. No tremor. Neck—no stiffness. No enlargements of glands. Triceps—jerks increased. Knee-jerks increased. Patellar clonus—nil. Ankle clonus—nil. Babinski's sign—nil. Abdominal reflex—present. Kernig's sign—absent. Gait—normal. Sensation—impaired (?) on the right leg. Heart—apex normal site, sounds—normal. Pulse regular—90 per minute. Blood pressure S/D—132/95 mm. of Hg. Lungs—normal. Respiration—26 per minute. Liver and spleen not enlarged. Extremities cold. Temperature—97°F. Lumbar puncture—25 c.c. clear fluid was drawn under pressure. Complete examination of the blood, urine and stools showed no abnormality except hookworm infection.

Cerebro-spinal fluid showed no cells except a few red blood corpuscles. Culture was sterile. Wassermann reaction was negative. Sugar content was 0.071 per cent and urea content—0.015 per cent. Globulin test was negative.

Case XIII.—A. R., a Mohammedan, male, aged 45 years, a tramway conductor, was admitted into the Carmichael Hospital for Tropical Diseases on the 26th December, 1935. He was on duty in a second class compartment of a tram car on the Chitpore line, when at about 10 a.m. he felt a tingling sensation on the right side of the head followed by giddiness and dim vision. He informed the conductor of the first class compartment about it, who at once stopped the car and had him taken out. He was held by several men and about fifty buckets of cold water were poured on his head. One of the members of the staff of the School happened to be passing by and saw the man shivering with cold and begging the people not to pour any more water. This was stopped and the patient was brought to the hospital.

Condition on admission.—Patient was shivering, undoubtedly due to cold. His body and extremities were cold. Temperature was 96°F., pulse 96, and respiration 28 per minute. He was fully conscious and had no complaint excepting shivering with cold. He was immediately put to bed and warmed up with blankets and hot water bottle and given hot milk. Within a short time he felt all right excepting slight pain in the left thigh.

Physical examination showed no abnormality except pyorrhœa alveolaris and some carious teeth. His blood pressure was—S/D—150/100 mm. of Hg. Lumbar puncture was done—18 c.c. of clear fluid was drawn off under pressure. The fluid was clear and contained no cells except a few red cells. Culture was

sterile. Globulin test was negative. Urine showed no abnormality. *Ascaris* ova were found in the stools. Further laboratory examinations showed no abnormality.

Case XIV.—A weaver in the Albion Jute Mills, Budge Budge, aged 50 years, was admitted on the 6th January, 1936.

Early in the morning, as he was waiting for the mill gate to open with other employes, he heard discussions regarding *jhin-jhinia* disease and of many deaths due to this disease.

He was perfectly fit when he started to his work. After about half an hour he felt giddy and a burning sensation all over the body. He also felt a little tingling about the right big toe. He put some water on his head himself. Then felt tingling in both feet again, and began to shiver; the other workers then poured cold water on his head. Next he was removed to the dispensary attached to the mill, where he was laid down and ice was applied on the head and spine. The doctor brought him to the Carmichael Hospital for Tropical Diseases for admission, under the instruction of Lieutenant-Colonel Denham White.

On admission, the patient's temperature was 98°, pulse 80 and respiration 20. He was shivering with cold. There was no congestion of the eyes. Excepting slight exaggeration of the knee-jerks and triceps jerks no abnormality was discovered. Blood pressure was systolic 130 and diastolic 90 mm. of Hg. Wassermann reaction was negative. Culture and other tests showed negative results. Stools showed hookworm ova, *Giardia* cysts, pus cells, and *Streptococcus faecalis*. Urine was normal.

Case XV.—P. J., a fireman, Tala Water Works, aged 40 years, U. P. man, Hindu, was admitted on the 8th January, 1936, at 1 p.m.

He had pain and tingling sensation in the great toe of right foot last evening but nothing happened during the night. The following morning, after having his breakfast he had a similar tingling sensation. He complained of it to other workers, who poured cold water on his head and body (about 10 buckets). A local doctor stopped it and sent him to the hospital.

Condition on admission—The patient was shivering, apparently due to cold. Body was cold and wet. Temperature was subnormal; pulse 96 and respiration 26. Eyes were normal. Knee-jerks were brisk on both sides. Other reflexes were normal. Blood pressure was 140/100 mm. of Hg.

Lumbar puncture—The cerebro-spinal fluid was clear. About 15 c.c. was removed, pressure normal. There were hardly any cells in it. Culture was sterile.

Sugar—0.064 per cent and chloride—0.713 per cent.

Urine was normal.

Globulin test was negative.

(Note.—This patient had 12 fingers and 12 toes.)

Case XVI.—A. K., a Mohammedan duftry, aged 28 years, was admitted on the 9th January, 1936, at 1-30 p.m. While he was working in a sitting position in his office at about 12 noon, he suddenly felt a tingling sensation in both his feet—which went up to his legs and thighs. Thinking that he had got *jhin-jhinia* he was taken under a tap and kept there for some time. Besides 5 seers of ice were applied on the head and spine. Then he was brought to the hospital. On admission he was found to be suffering from the effects of treatment. Physical examination did not reveal any abnormality. Knee-jerks were normal. Excepting eosinophilia of 10 per cent there was nothing particular in the laboratory findings.

Case XVII.—A. A., a Mohammedan male, an inkman of a printing press at Shibpore, was admitted on 10th January, 1936, at 12-30 p.m.

While attending his duty, he felt a tingling in his toes spreading up to the thigh. He was said to have dropped down unconscious. Water was poured on him when he became conscious.

On admission the patient was cold and clammy and shivering with cold.

Temperature was 96°F., pulse 72 and respiration 18 per minute. Eyes were normal. Excepting slight exaggeration of deep reflexes, there were no abnormal clinical findings.

On lumbar puncture clear cerebro-spinal fluid was drawn with normal pressure. Hookworm ova in the stools were the only positive laboratory findings.

Blood counts were done in all the above cases; excepting slight eosinophilia, in some cases which is apparently due to associated conditions, the results were normal. Tissue culture carried on with the plasma and cerebro-spinal fluid of the cases treated in the hospital showed no change.

Discussion

A perusal of the above records would show that the features commonly met with in this 'disease' are mostly subjective sensations, *viz.*, tingling, cramps, hot burning sensation, etc., followed by a shivering of the body. They are of short duration, and physical examination of the patients revealed minor abnormalities only. These would be found even if a series of persons not suffering from the disease were examined. The only ones of some interest are a tendency to exaggeration of knee-jerks and increase in the pressure of cerebro-spinal fluid in certain cases. The latter, though of more importance than the former, can occur in various conditions, *viz.*, paroxysmal cough, severe exertion, prolonged crying, etc. The effect of severe chill and exertion as a result of the water treatment can account for the increase of pressure of the cerebro-spinal fluid.

Undoubtedly there has been a panic prevailing among the people. There is practically no evidence to show that the disease is any organic disease syndrome recognized in scientific medicine. The majority of the cases of this so-called disease seen in the hospitals in Calcutta have been either cases of some definite diagnosable organic disease, such as epilepsy, apoplexy, malaria, poisoning, or have been apparently normal individuals suffering from the effects of treatment for this so-called disease, that they have received outside. When they had recovered from the effects of treatment they had no more subjective symptoms and were quite fit to be discharged from the hospital. All these patients had heard about *jhin-jhinia*, had discussed it with their companions, and knew the symptoms that were supposed to be associated with this so-called disease. It is impossible to escape the conclusion that in the cases investigated by us the affection was of a purely functional nature. Even in the severest form it produced no mortality and the symptoms were of short duration. There is no justification for the panic and the drastic treatment adopted by the people is not only wrong but harmful.

Absence of any definite neurological signs rule out encephalitis. It was suggested by certain health authorities that the condition might be acute lymphocytic choreomeningitis as reported in America. The main feature of the

TECHNIQUE FOR PUTTING UP FRACTURE OF THE CLAVICLE

By R. L. RAYMOND
CAPTAIN, I.M.S.

Indian Military Hospital, Quetta

ALL the best-known methods of splinting a fractured clavicle are imperfect in their application, except perhaps Bohler's method which I have not tried, because it needs special apparatus and looks complicated and cumbersome.

Sayre's method allows the shoulder to drop and does not properly control the outer fragment. When much leverage on the first turn of strapping on the arm is necessary to reduce the overlapping of the fragments and maintain reduction the arm becomes very swollen and the skin abraded, and very often the patient cannot tolerate the appliance.

The clavicular cross is cumbersome and the lower end where it impinges on the sacrum tends to slip downwards and to carry the

(Continued from previous page)

latter condition is that of an infection of the upper respiratory tract followed by meningeal symptoms which are ushered in by sudden onset with headache, nausea or vomiting, rise in temperature to 100° to 103°F., stiff neck and a positive Kernig's sign. The disease runs a benign course for about 10 days to 2 weeks. The temperature declines by lysis. The cerebrospinal fluid is under increased pressure; its cells are considerably increased. This cellular response is almost entirely lymphocytic. A comparative study of the two conditions will convince any impartial observer that they are not the same.

Conclusions

From the cases of the so-called mystery disease, *jhin-jhinia*, we have recently studied, we have formed the opinion that it is very doubtful if it is a disease entity at all. There was a panic prevailing among the people and any of the ordinary diseases such as malaria, epilepsy, hysteria, neurosis, apoplexy and the like were diagnosed as the so-called mystery disease. The panic was intensified by articles in the press and by different forms of treatment which were extensively advertised.

In this connection we would like to draw attention to the fact that a mystery disease called *makawlen* appeared in Burma eight or nine years ago and the Government went so far as to appoint a committee to investigate the condition. The conclusions of this committee were that *makawlen* was more of interest to the psychologist than to the pathologist; it actually turned out to be nothing but malaria and the eruptions around the anus which were supposed to accompany the disease were never seen by any medical man.

shoulders with it, and the ideal upward and backward position of the shoulders is lost.

In Desault's method, with a wedge in the axilla, the vessels and nerves tend to be seriously pressed upon, and as in Sayre's method the

shoulder joint is fixed and tends to become stiff, at least temporarily.

Treatment in bed with a sand-bag or pillow between the shoulders or by extension on the abducted arm are both unnecessarily exacting experiences.

In a limited series of cases in Quetta it has been found both simple, expeditious and extremely effective to put these cases up in a figure-of-eight plaster bandage passing between the shoulders posteriorly and drawing them well back. When pain prevents the assumption

of a satisfactory position before applying the bandage the fracture can be injected with 2 per cent novocaine.

It is important to apply the plaster as a prepared soft splint which can be moulded into position, and not as a roller bandage, as the latter rolls up into a ropy mass in the axillæ. This cuts into the tissues, does not keep the shoulders back so well, and the technique is not so simple. A thoroughly wet strip 6 feet by 3 inches and about 12 layers thick is made by unrolling backwards and forwards and rubbing the plaster in.

The axillæ and shoulders are very well padded with cotton-wool and with the shoulders held well back and upward by the patient and an assistant, the plaster splint is applied as a figure of eight between the shoulders with a little tension. It is moulded well into the curves of the part except actually in the axillæ where the plaster is not allowed to roll up. This latter procedure keeps the arm held a little way from the side, which position is a distinct aid in maintaining the upward and backward position of the shoulders. Finally a few turns of a plaster bandage over the shoulder where the plaster splint terminates, fixes the free end.

When the plaster has hardened it not only keeps the shoulders immovably fixed in a backward position without any fear of bandage slipping or stretching, but the rigidity of the plaster and the broad bulky mass in the axillæ does in actual fact preserve a perfect elevation of the shoulders.

NATURAL *SPIRILLUM MINUS* INFECTION IN WHITE MICE

By R. KNOWLES, C.I.E.

LIEUTENANT-COLONEL, I.M.S.

Professor of Protozoology

ASSISTANT SURGEON B. M. DAS GUPTA

Assistant Professor of Protozoology

and

S. SEN, M.B. (Cal.), D.T.M. (Bengal)

Clinical Pathologist, Calcutta School of Tropical Medicine

THE following incident may serve as a warning to other laboratory workers in India engaged in the study of rat-bite fever.

J. H. C., an Anglo-Indian male, resident in Calcutta, aged 28 years, was admitted to the Carmichael Hospital for Tropical Diseases on the 25th October, 1935, suffering from daily intermittent fever, rising to 103°F. or even higher, with rigors and vague pain in the left lumbar region. The fever had persisted for approximately one year before the patient's admission to hospital. Every possible clinical and laboratory examination was carried out, but no diagnosis could be made.

The patient keeps a tame squirrel, and it seemed possible that this squirrel might have become infected with *Spirillum minus*—the organism of rat-bite fever, which is known to infect rodents other than the rat—and have conveyed the infection to the patient. (There was no history of a rat bite at all.)

Accordingly, on the 28th November, the patient's blood was inoculated intraperitoneally into a white mouse (*Mus leucopus*). On the 7th December the blood of this mouse showed *Spirillum minus*—a moderately heavy infection. The diagnosis now appeared to be clear; rat-bite fever, probably contracted from a bite by the tame squirrel.

Two intravenous injections of novarsenobillon were next given, but the fever still persisted at its original level. Accordingly, at different intervals of time five other white mice were inoculated with the patient's blood. To our great surprise every one of these five mice later showed *Spirillum minus* infection.

(Continued from previous column)

It is not necessary to apply a sling, as the patient, for his own comfort's sake, rests his hands on his hips, or on the knees while sitting or squatting.

This form of fixation leaves the arms free and there is no loss of function at the shoulder joint.

In contrast to other methods of splinting this method is simple, needs no apparatus, keeps the shoulders well up and back without any chance of moving, preserves the alignment of the fragments, and leaves the arm free for active movements.

We were now faced with three possibilities, viz :—

(i) Was the batch of novarsenobillon used inactive? This appeared to be unlikely; as it had been issued by the Medical Storekeeper to Government with the usual certificate.

(ii) Was the strain of *Spirillum minus* an arsenic-resistant one? We had never read or heard of such a strain, but it seemed not impossible.

(iii) Were the white mice concerned already naturally infected with *Spirillum minus*?

being naturally infected, and used young guinea-pigs as control animals.

We next decided to test the pathogenicity of this mouse strain. Having obtained an adult male Hindu volunteer, he was put to bed in the hospital and carefully examined. He gave no history of rat bite, and showed no cutaneous lesions. His temperature was normal, and examination of his blood under the darkground and in thin and thick films showed no parasites.

The next day—29th January, 1936—the tail of a white mouse showing natural infection with

CHART

Mouse strain of *Spirillum minus*. Temperature chart of human volunteer.

We decided to test the third possibility first. The white mice concerned were part of a batch of 100 received some months previously from the Central Research Institute, Kasauli. On receipt at the School the white mice had been caged in fours in capacious cages of narrow meshed galvanized iron netting—five meshes to the inch. No rat could possibly have got at the mice under these circumstances to bite them.

There were 31 mice of this batch left in the animal house; these had received no inoculation of any sort, and had not been used for any experimental purpose. The blood of each of these 31 mice was now examined twice, on each occasion under the darkground illumination and in thin stained blood films. To our surprise we found that at the first examination no less than 14 showed natural infection with *Spirillum minus*, whilst the second examination showed a fifteenth mouse also infected. In other words no less than 48 per cent of this batch of white mice showed a natural infection with *Spirillum minus*; a state of affairs which, from our knowledge of the literature, we believe to be without precedent.

On looking through the literature we found that Robertson (1930) recorded that he had found four white mice naturally infected since 1924. (The number of white mice examined is not recorded, but was presumably large, since Professor Robertson has been working on rat-bite fever for several years). Das Gupta and Chatterjee (1933), in describing previously undetected *Spirillum minus* infection in the nasal secretion of patients with anæsthetic leprosy, drew attention to the possibility of white mice

Spirillum minus was cleaned with absolute alcohol and then thoroughly washed with sterile saline to remove all traces of alcohol. The end of the tail was then snipped off with a pair of

fine scissors. A few drops of blood were collected on a sterile watch glass, diluted with a little sterile saline, the whole aspirated into a sterile hypodermic syringe and inoculated intradermally into the right arm of the human volunteer.

On the sixth day after this inoculation the patient showed a temperature of 100°F. After this he ran a typical rat-bite fever course with five or six relapses, as shown in the temperature chart.

On the seventh day after inoculation the skin around the site of inoculation became red, painful and œdematous—the appearances being as shown in the photograph. The axillary glands draining the site of the lesion also became enlarged and tender.

No spirilla could be detected in the serous exudate from the site of the inoculation. On the ninth day after the inoculation, however, blood was taken from the patient at the height of the febrile phase and inoculated intraperitoneally into a young guinea-pig—whose blood had twice previously been examined with negative results. This guinea-pig showed *Spirillum minus* in its peritoneal fluid eight days later, and in its blood on the eleventh day.

This mouse strain of *Spirillum minus* was thus proved to be pathogenic to man. Twenty-eight days after inoculation, and during an acute febrile relapse, the patient was treated

with novarsenobillon intravenously and made a rapid recovery.

From this experience it is quite clear that the white mouse may not be a reliable animal for blood injection in the test for *Spirillum minus* infection. We have now commenced searching the blood of young guinea-pigs, both under the darkground, and in stained blood films, and have found no infection in the first 20 so far examined.

Summary

Fifteen out of 31 white mice—or 48 per cent—were found to be suffering from natural infection with *Spirillum minus*, and it has been demonstrated that this mouse strain is pathogenic to man. It thus becomes evident that the white mouse may not be a reliable animal for blood inoculation in testing for rat-bite fever.

Our special thanks are due to Bt.-Colonel R. N. Chopra, C.I.E., K.H.P., I.M.S., Director of the School, and to our colleagues on the staff for permission to use the notes on the case.

A Mirror of Hospital Practice

A PECULIAR COMPLICATION OF LABOUR*

By A. S. GILL, L.M.P.

Sub-Assistant Surgeon, Civil Hospital, Thabeitkyin

ON the 11th December, 1934, I was called to see a confinement which was being attended to by a competent midwife. The patient was a 25 years Burmese woman of rather a delicate constitution, second para, normal previous labour with a healthy child and without history of any abortion or miscarriage. She had been in labour for the previous 18 hours. The midwife informed me that the os was fully dilated but that the head would not descend. At the same time she pointed to an irregular bulging of the uterus towards the right costal margin. The general condition of the patient was quite satisfactory, pulse—92, respiration—24, temperature—normal, pains weak and infrequent.

Abdominal palpation showed the uterus to be out of tone, irregular and with a bulging curvature of the

upper right quadrant. Vaginal examination showed a fully-dilated os, head fixed in L. O. A. position, and no apparent disproportion between the head and the passages. The bulging was very puzzling. A more extensive palpation, percussion and auscultation brought out the fact that it was the liver adhering to the uterus and had followed it downwards right out of the hypochondrium and its upper surface could be palpated easily. The normal liver area was partly occupied above by the lung resonance; this situation caused anxiety on account of the possibility of post-partum hæmorrhage. There was no history suggesting a diagnosis of old peritonitis.

Half a cubic centimetre of pituitrin was injected. It was immediately followed by vigorous uterine contraction and within 10 minutes a healthy male child was born followed within another 15 minutes by the entire placenta, fortunately without any hæmorrhage. Two drams of liquid extract of ergot were given and repeated after half an hour. The liver remained where it was and did not give trouble to the patient who was none the worse for all this. On my second visit, about eight hours after delivery, I found all the organs, lung, liver and the uterus, in their normal places and the patient had a perfectly normal puerperium.

Indian Medical Gazette

APRIL

TROPICAL TYPHUS

It is against the policy of this journal to enter into any discussion on controversial matters, of a political or even a semi-political nature, and we do not propose to discuss here whether the army in India is a burden to the tax-payer or whether as an insurance against invasion and internal disturbances it is well worth the money it costs. We do, however, wish to emphasize one way in which the army has been in the past, and still is, invaluable to the civil population—namely, as a detector of endemic disease—in a passive rather than an active capacity. Soldiers in this country, whether they be British or Indian, are usually—in the former case always of course—foreigners in the part of the country in which they are stationed; thus they enjoy no immunity against the local strains of infecting organisms, and are not only more liable to be attacked but when they are attacked they react to the infection with severe and usually classical symptoms.

There are of course many examples of this 'detecting' power of the British troops in India. Typhoid fever was at one time unrecognized in Indians, mainly because they seldom suffered from a classical attack, but amongst the British troops it was for many years one of the most important causes of mortality; attention having been drawn to it, typhoid is now recognized as a common disease amongst the civil population. Another example is kala-azar, or 'Dum-Dum fever'—this was recognized as a clinical entity in the army at a time when it was considered by Ross and other workers in India to be a severe form of malaria, and it was from the spleen of a British soldier who had contracted the disease at Dum-Dum that the causative parasite was first recovered.

A recent example is typhus; the sporadic incidence of the disease had been noted, in fact following the infection of the most distinguished of this journal's editors, apparently by a tick, our editorial columns suffered a severe attack of 'tick typhus', and the earliest reference to tropical typhus, which has now been recognized and studied intensively in other tropical countries, will be found in the volumes of this journal. The widespread existence of this infection in India has, however, again been indicated by the army, and in a contribution that appears in the November and December (1935) numbers of the *Journal of the Royal Army Medical Corps*, Major J. S. K. Boyd has analysed the reports on 110 cases that have occurred in the army—or in persons associated with the army—during the year 1934.

Sir John Megaw has suggested that the typhus fevers should be classified according to which insect vector transmits the virus from patient to patient; thus he considers that the classical epidemic typhus transmitted by the louse should be called louse-borne typhus, Brill's disease should be called flea-borne typhus, tsutsugamushi disease—mite-borne typhus, Rocky Mountain spotted fever—tick-borne typhus, and that there should be a group for typhus of an unknown vector. There are many points in favour of this classification, one being that the clinical picture varies according to the vector and that there is evidence to suggest that the virus is in some way modified by the vector that transmits it. The great objection to this classification from the practical point of view is that it is very difficult to be certain in any particular case what the vector was. Sir John suggested that the disease in India should be called Indian tick typhus because in some of the cases described there was a definite history of tick bite and that in most of them there was a reasonable chance that the patient had been bitten by a tick.

Major Boyd attempted to classify his cases according to the vector, but immediately came up against this difficulty, namely, that in almost every case there was no evidence what the insect vector was or even whether an insect vector had been concerned, so that an attempt to separate the cases into groups by this means failed.

The study of typhus during the last quarter of a century has been simplified by the observation that in the blood of patients suffering from this disease there is an antigen active against certain organisms of the proteus group; the presence of this antigen seems to be a fortunate accident because, although these organisms are from time to time isolated from patients, no direct aetiological association with this disease has ever been proved against them. Further help has come from the more recent observations that the different clinical types of typhus are distinguishable by the presence of agglutinins against different strains of proteus. Taking advantage of this observation Major Boyd has divided his cases into three antigenic groups according to whether the patient's serum produces the maximum agglutination with the XK, the X2, or the X19 strain of proteus, and he has subdivided his last group on geographical and clinical grounds. He has thus been able to divide his cases into four provisional groups and in his paper he has studied the epidemiology, the symptomatology, and the laboratory findings in each of these groups separately. These he has summarized in a table which we give below.

There is of course a considerable amount of overlapping in these different groups, and in his conclusions he does not take the view that his

four provisional groups should be considered to represent four different types of the disease, but he thinks that the evidence points to there being at least two, if not three, distinct types of typhus endemic in India. The first is the type in which the XK antigen is present. About this being a distinct type there seems to be very little doubt; it has a symptomatology quite distinct from that of the other type or types, a different seasonal distribution, and the agglutination results are clear cut, there being a strong XK reaction and no agglutination at all with X2 or X19. We quote below a clinical description of this type of the disease:—

'Severe headache was a very constant and early symptom. The face was usually flushed, and the conjunctivæ somewhat injected. Rigors and sweats were common in the early stages, and toxæmia, with its accompanying symptoms of lassitude and drowsiness, was of varying severity. Severe pains in the joints, or "all over the body", occurred in several cases.

The rash was by no means a constant feature, being present in only 15 of the 21 British cases, and in only 1 of the 14 Indian cases. It usually appeared on the

fifth or sixth day, but was recorded as early as the first and as late as the eighth day of illness.

In all cases in which it appeared, the rash was of the type described by Macnamara, and no excuse is made for quoting his excellent description verbatim.

"The rash appears on the fifth day of the disease. A flush may be present on the fourth day. This may be demonstrated on an apparently normal skin by the pressure of the hand. The paler impression produced by the palm and fingers persists on the skin. The rash is that of true typhus, though the lenticular papules have not been observed. It is a dusky erythema, with scattered irregular blotchy underlying macules, purple in colour. The macules persist on pressure in some degree, while the flush fades, leaving the skin very pale by contrast. In severe rashes the macules sometimes appear raised, but cannot be felt. The rash is best seen in the umbilical and epigastric areas, and over the lower ribs. It extends to the sides of the thorax. The distribution of the flush is wider, it is well marked over the trunk, with the exception of the upper part of the front of the thorax, and the hypogastric and iliac areas. It is particularly well seen on the back and between the shoulder blades. The rash has been seen on the upper and lower limbs, but usually these are not affected. It is not very striking in appearance, and may not be noticed. It fades gradually, the flush disappearing earlier than the

macules. As a rule it is no longer visible at the termination of the pyrexia."

It is worthy of note that in no case of this series did the rash become papular or petechial, nor, with one exception, did the macules extend beyond the trunk. The macules were found chiefly on the abdomen and thorax; the face and neck and extremities were unaffected.

The inconspicuous nature of the rash no doubt affords the explanation of its apparent rarity in Indian patients, as it is presumably obscured by the pigmented skin.

The average duration of the rash, calculated from figures given in thirteen cases, was seven days. There was, however, difficulty in determining the exact time when it could be said to have disappeared.

Complications and sequelæ were by no means common [*sic*, ? uncommon]. Nine cases showed pulmonary symptoms, five developing bronchitis, two pneumonic symptoms, and two pleurisy. Three cases developed acute mental symptoms and two others varying degrees of transient paralysis.

The average duration of fever (33 cases) was 14.2 days. During the pyrexial period the pulse rate was relatively slow, resembling in this respect fevers of the enteric group.

Recovery was by lysis, and in some cases by crisis. In uncomplicated cases all other symptoms disappeared and convalescence was rapid as soon as the fever subsided.

The average stay in hospital (35 cases) was thirty-one days'.

He considers that there is a strong clinical resemblance between the X2 group and the Poona-Ahmednagar group, and he does not attach any great importance to their antigenic differences; X2 and X19 are antigenically closely associated organisms and it has been shown in other endemic areas, where a number of people were obviously suffering from the same disease, that the serum of one patient would agglutinate X2 in high titre and X19 scarcely at all, whereas that of another would do the reverse.

From a clinical point of view the main difference between this second group and the XK group is in the rash. This is a constant finding in the X2 Poona-Ahmednagar group, even amongst the Indian cases, it is a florid, very marked rash, in some cases becoming raised and papular, it is generalized and not confined to the trunk; and it appears earlier, lasts longer and usually leaves a stain behind.

The Bangalore group are distinguished from the other group agglutinating X19 by the fact that that agglutination is in very much higher dilution, that the rash is a comparatively rare feature and less marked when it occurs, never becoming papular, and is evanescent, and that the whole disease is very much milder; this group Major Boyd thinks resembles Brill's disease, the flea-borne typhus.

Valuable as this study has been for showing the widespread distribution of the disease in India, it has provided practically no clues as to the nature of the vector. There was little evidence that a tick was the vector in any single case and in a number the possibility of a tick bite seemed to be definitely ruled out.

Little progress in controlling the disease can be made until we know the vector or vectors,

and we are glad to see that the subject is engaging the attention of research workers in this country. Some of the preliminary work on this subject carried out by Colonel Shortt was reported in our January issue and in the January number of the *Indian Journal of Medical Research* there are three papers on the same subject by Colonel Covell.

The former was able to show that the blood of the Kasauli squirrels agglutinated the OXK strain of proteus in much higher dilution than did that of the squirrels collected from the plains, whereas both sets of animals were almost entirely negative to the OX2 and OX19 strains. He also showed that the Kasauli squirrels harboured fleas, whereas the plains squirrels harboured lice.

Colonel Covell isolated a strain of typhus virus, which he was able to maintain by passing through guinea-pigs, apparently indefinitely (up to 10 passages at the time of writing), and he also isolated a typhus strain from a rat flea.

There are of course many insects and many possible carriers to be investigated, but parasitic insects that come in contact with man are more limited and, as Colonel Shortt has pointed out, it seems probable that if these were investigated systematically it should be possible to pick out the potential vectors. The finding of the carrier—and from the sporadic nature of the incidence of the disease it seems probable that the infection is maintained by an alternative host—may present a more difficult problem as this may be some animal that does not come into close contact with man; some domestic animal such as the dog may itself be immune and yet transport the infected insect into human quarters.

There is strong evidence to suggest that there are at least two types of typhus—this is a point about which all the workers we have mentioned are agreed—and it is very probable that each will have its vector and each its natural host, so that a promising vista for research in this disease is opened up.

Commentary

RATS, LICE AND HISTORY

PROFESSOR ZINSSER'S book* is a, or perhaps the, Philosophy of Louseydom: nay, rather the encyclopædia of the subject, the only apparent omissions being any note of the Laplanders' custom of boiling lice in milk with plenty of salt and taking the decoction on

*Rats, Lice and History. (Being a Study in Biography, which after Twelve Preliminary Chapters indispensable for the preparation of the Lay Reader, deals with the Life History of *TYPHUS FEVER*). By Hans Zinsser. 1935. George Routledge and Sons, Limited, London. Pp. xii plus 301. Price, 10s. 6d.

an empty stomach for the cure of 'jaundice', and of Shipley's citation of Theo. Hook:—

'Her ladyship said when I went to her house
She did not regard me three skips of a louse,
I freely forgave what the dear creature said,
For ladies will talk of what runs in their head.'

The essence of the philosophy is a regard for typhus fever as the emblem of 'a protoplasmic continuity' throughout the ages influencing the lives of men, and the author has been led to cast his discourse in the form of a life-history of the adventurous career of his putative hero, Rickettsia, during birth, adolescence and maturity—His death not yet! This biographical fiction is perhaps the only thing in the book that may intrigue the reader. The subject by very token of the philosophy is an immortal, yet a biography in plain English means a story of but the vegetative and slough-destined mortal coil, the reason indeed why one finds, as the author has, that this method of literature goes 'into competition with the erotic memoir' and that its mines of information are 'keyhole indiscretions and other lucubrations'.

Perhaps, however, the author may be allowed with W. S. Gilbert, Lewis Carroll and other artists the licence of clothing his blythe spirit in fancy dress. Anyway, his plot is certain to be a source of delight to the reader for it first leads him into a whimsical dissertation on the modes of biography, he reviews the classical models to the disadvantage of the modernists 'who sit between intelligence and beauty without possessing either' and who burn their fingers with 'Freudian high explosives' and 'appraise their heroes by their endocrine balances rather than by their performances'. 'Poor Shelley, poor Jesus', if it is to be their lot to have '*les petites choses de la vie privée*' exposed to the vulgar gaze. Of course the author chooses the classical model and claims that his subject needs no such assistance as 'psychoanalysis—mother complexes—early love affairs or later infidelities—perversions—the *réclame* of a libel suit barely averted—epidemiologists who talk like the hero of Arrowsmith'—and so on. Nevertheless, the public composed of such as doctors, bookbinders, ministers, and trained nurses want this sort of stuff at the end of a dull day, and so the modernists are not to be blamed overmuch for supplying it. One writer has tried both methods, sometimes satisfying the reasonably intelligent and sometimes 'luring a fat cheque with a story about the poor boy and boss's daughter'.

Then stung by a taunt that biography is work for an artist and not for a scientist the author goes into a flat spin. He protests against the stain-glass attitude of a specialist having no interest beyond his chosen field unless in 'contract bridge' and holds that one type of intelligent occupation increases the capacity for comprehension in general. In any case the essential difference between Art and Science cannot be stated; they are merely at opposite ends of the spectrum of human perception, one grading into the other, while 'beyond one end the senses give out and the physicist joins the Church; beyond the other the artist's brain collapses'; for instance he who perpetrated 'Balloons—coloured balloons—my coloured balloons—balloon balloons—they have punctured my categorical imperative' wrote of the spectrum, and vulcanizing the puncture would have done no good. Even those like Eddington, protagonists of 'mathematical science', 'are constrained to sit down comfortably in their metaphysical toboggans and swish back into the warm vales of theology, they scamper back to God'. 'Kepler being a noble exception, he never wrote a book about God'. Still on this point the author has it that both scientist and artist accomplish no more than a new understanding of things that have always been. They are both observers of Nature and their achievements become Science or Art according to the degree to which the emotion or reason is impressed by them.

In consequence, on thinking over these things the author, luckily for the reader, decided it was safe for

him to write *A biography of typhus* and with a Parthian shaft wished that some of the psycho-analytical biographers could get psychic carbuncles and the lucubrations writers of sexual neuropathics develop infection while playing with *Treponema* as easily as an anatomist can contract it while doing his honest work.

The author has many more digressions from his thesis, but just as important to the understanding of it as are physiology and chemistry to the Art of Medicine. The only pity is he stopped short of many that he provokingly only hints at, for instance on the origin of life he has it 'We all know already that it is a physico-chemical process though we have not yet succeeded in imitating it. And when we do we shall be philosophically just about where we are now'. The author excuses himself for such digressions on the ground that one Pierre Beyle has footnotes four times the length of his text!

Coming now to the biography of his hero and first his gestation in the womb of time he learns something of it from considering that any disease 'represents complex biological interadaptations and interactions covering thousands of years!' He thinks that the louse as a factor in the transmission of typhus arose from an actual discovery by the insect of blood beneath its normal epidermal diet, just as Bobo discovered that roast sucking-pig was food fit for kings and for Bobo, and further he sets forth the evidence of the medical laboratory in an attempt to elucidate the steps in the evolution of the condition, aided by researches in the laboratory of history. The latter method has forced him to ascertain how other diseases have behaved, sometimes appearing whence nobody knows, reaching a zenith and disappearing entirely and equally mysteriously—the disappearance of plague from Europe is not so inexplicable on the theory that the sewer rat exterminated the black rat and removed its close contact with man—or perhaps undergoing mutations, as in the neurotropism that has manifested itself in certain virus diseases such as vacciniasis.

His historical enquiries have led him to delve into the Ayurveda from which he learnt of fevers including malaria, and of cholera. On the subject of acquired tolerance he says 'another 1,000 years might produce a condition in which a peritoneal puncture of almost any *bon vivant* would reveal *T. pallidum* of which the host was all but unconscious. Arsphenamin has now probably ruined that prospect'.

Here indeed is a dissertation on a disease that should be read by all those who want to know not only of the local and present-day genesis of epidemics during their maturity but of their rise and fall as of the rise and fall of Nations. The author's scholarly methods cannot be too carefully studied.

In this crystallization of colloid material these *litteræ humaniores* are embellished with all the figures of speech that go to adorn a tale and to teach profound wisdom to crude minds. The author gets down to his 'muttons' garnished with *saucé piquante*. Every page ripples with aphorisms, axioms, epigrams, delicate ironies, laughter, *obiter dicta*, pretty wit, soothsayings, whimsical 'whimso whamsos' and here are some of the bonbouches (*anglicé*) more or less paraphrased. 'It was bad manners to kill fleas and lice in front of people, at any rate if you did not know them very well'. 'Would Cortez have burned his ships if his wife had been with him? No, he would have gone as far as Orizaba, returned to Spain, and written a book, *Hernando and Juana look at Mexico*'. 'Lice have been important in politics. Persons eligible for the mayoralty of a town would sit round a table with their beards resting on it. A louse would then be placed in the centre of the table and he to whom the louse went was the next mayor'. 'Nature has provided that the nymph of the louse, that is during its high school or flapper age is not yet possessed of sexual organs'—the louse by adapting itself to parasitism has attained the ideal of bourgeois civilization'. 'Bufon and Linnaeus were by this time famous and most likely were occupied in attending Conferences' [sic]. 'The Brown Rat appears to have

had a hard time in 'thrifty' countries. In Scotland it took 60 years to go from Selkirk to Morayshire and has never done very well among the Switzers'—it is obvious that Religion begins where Philosophy takes off from the solid shore of the exact sciences into speculative waters, the shallows of which are metaphysics—citing Shelley 'to analyse a work of art into its elements is as useless as throwing a violet into a crucible'. 'Africa is a playground for museum administrators and their wives, who go there to have their pictures taken with one foot on a dead lion, while disgusted-looking bearers carry boxes of champagne and biscuits on their heads'. 'The louse does not become sexually mature till.....but, then, Oh Boy!' 'The speculation has arisen among religiously-minded louse-scholars as to whether Adam and Eve—the neatest pair that ever joined hands, were lousy'—'in Northern Siberia young women sportingly threw lice at a traveller, who ascertained that this indicated love—a sort of my louse is your louse ceremony!' Let it be remarked that they were head lice.

Many examples among men who were not too unlike rats can be cited. Sam Wesley had 14 children with his good Sukey before he left her because she refused to pray for the lawful King. Then on the accession

of Queen Anne he was reconciled to Sukey and 'bestowed 5 more children on the fortunate woman'. 'Man and rat are utterly destructive, taking all that Nature offers; it is likely, biographically speaking, that the evolution towards higher things may gain velocity with time and that in another 100,000 years the comparison of men with rats may be less humiliatingly obvious'.

This commentary is composed mainly of citations from the book, but there are in it, say, forty times as much again of such good things and, quite apart from the pleasure of reading such a work of art—the spectrum shows the colours of Science and Art combined, there is that in it to make the Doctor worthy of his honorific and less of a *Kauffman*.

If the author modestly felt, when making certain criticisms of a brither Scot, like Neanderthal Man attacking a Mastodon with a peashooter, the reviewer feels rather like the Mayor's daughter when presenting the Princess with a posy.

SHORT-WAVE THERAPY

By RUDOLF TREU, M.D. (Cologne)
Calcutta

THE use of long-wave currents with high frequencies or diathermy is now fairly well established in medical practice, but, during the last few years, the apparatus used in electro-medical technique has been considerably improved and further developed. It is now possible to produce waves of greatly reduced length with a corresponding increase in frequency. These have recently been applied therapeutically in practice. Schliephake, as the author of several essential suggestions regarding the method of applying ultra-short waves in therapy, has deservedly earned a great reputation. It was he who first introduced the use of short waves, on a large scale, into the therapy of various diseases.

At a frequency of approximately 1,000,000 per second, diathermic currents have an average wave-length of from three to four hundred metres, whereas short waves have a range of from 15 to 100 metres with a corresponding increase in frequency. Waves under 15 metres in length are designated ultra-short, their frequencies rising to 100,000,000 and even higher. In order to avoid such big numbers in connection with ultra-short waves, in practical use reference is confined to the wave-length. Naturally, the frequency, corresponding to the speed of electricity (300,000 kilometres per second), is a multiple of the wave-length. Just lately, apparatus has been constructed which makes it possible to use waves only a few centimetres in length. In this case the experimental stage has not yet been concluded. It is quite

possible that further and altogether new therapeutic possibilities may eventuate when these transmitters are further improved.

There are two methods of producing short and ultra-short waves—spark-gap, and valve apparatus. The waves produced by each of these differ to some extent. Spark-gap apparatus produces so-called 'damped' waves, that is, the amplitude of oscillation is uneven. On the other hand, valve apparatus produces undamped waves, the oscillation in this case being even. While this distinction is important from the technical point of view, it has not as yet affected actual practice as both types of apparatus have been used to a similar extent. Of late, however, valve apparatus has been increasingly used in spite of the fact that this type and its use is more expensive than the spark-gap apparatus. The problem thus raised and many others have, at present, not been finally settled.

What is the fundamental difference in practice between long and short waves? In both cases, the production of so-called Joule's heat is aimed at. In other words, electrical energy is transformed into heat when the current passes through a medium such as the human body, which is a bad conductor. By introducing currents of very high frequencies it became possible to administer sufficient quantities of electrical energy to the body without causing any unpleasant sensations, provided that there is close contact between the body and electrodes. Should the contact be incomplete or unequal at any point, diathermic currents are liable to produce sparks or local burns. In addition to this the long-wave diathermic current does not distribute the heat evenly through the body, as the current follows the path of least resistance,

viz., vessels, nerves and muscles which are particularly well heated. On the other hand, those parts of the body which possess greater resistance, such as the bones, are much less heated. In the case of short and ultra-short waves, however, this is not the case. The heat penetrates the body in straight lines without following special conductors. A body between the electrodes of a short-wave transmitter is evenly heated throughout and electrical contact is not even necessary. On the contrary, the heat in the interior of the body is far more evenly distributed if the electrodes are fixed at a certain distance from the body. This has the advantage of precluding possible overheating of the skin and burning. Electro-physically the electrodes thus held at a certain distance from the body act as condensers. The body remains within the condenser field without actual contact between the skin and the electrodes.

Needless to say, such treatment without direct contact involves considerable electrical losses, and correspondingly higher current energies are required to make up the deficiency in resultant heat. As a rule spark-gap apparatus is not adequate for this type of treatment. In practice the gap between the electrodes and the body is produced by the use of a layer of felt, or, in some cases, the clothing of the patient is used for this purpose. Glass electrodes, suggested by Schliephake, permit regulation of the distance at will. They consist of a glass vessel, containing a movable electrode, which is placed on the body. The distance of these electrodes from the body may be varied from half to five centimetres.

In order to understand the effect of the short waves better, their action in the body may be considered. Diathermic currents are distinguished from galvanic and faradic currents in their physiological effects, in so far only as they do not irritate the sensory or motor nerves. For the rest, the principles which apply to Ohm's Law and Kirchhoff's Law of distribution (according to which the current follows the path of least resistance) are also valid in the case of diathermic currents. This does not hold good in the case of currents of ultra-high frequency. There is no difference between good and bad conductors, for even the bones, well known as the worst conductors in the body, are traversed by the current and heated. To achieve this with diathermic currents was formerly almost impossible.

Some other important qualities must now be noted. Diathermic current is not able to pass through the red blood corpuscles surrounded by a cell membrane. According to Ohm's Law it passes through the serum, and the blood corpuscles are heated only to the extent that the serum is heated. The ultra-short-wave currents, however, easily traverse the cell membranes and thus they warm the red corpuscles in their interior. It has even been stated that the blood

corpuscles are heated to a higher degree than the serum. Similarly, cells of varying structure are differently heated, while it is possible that the cell nucleus may also be heated differently from the protoplasm around it. The same applies to the heating of colloidal solutions. Whereas a watery solution of egg albumin coagulates at a temperature of 62°C., when heated by ultra-short waves an opalescence may already be observed at only 57°C. The explanation is that the molecules of the albumin have already reached a temperature of 62 degrees and coagulate, although the medium of the solution has only been heated to a temperature of 57°C.

Similar conditions may be observed when experimenting with bacteria. Schliephake noticed that staphylococci, which die in a water bath at 55°C., when inoculated into dead bodies died at a temperature of only 40°C. in the surrounding tissue. However, tests, taken from controls which had not been treated, yielded very good sub-cultures. Liebesny made extensive experiments, which showed that quite different wave-lengths were required in order to kill different micro-organisms. This, no doubt, will be of the utmost importance in practical therapy.

Quite recently, specific effects were observed on particular groups of body cells. When traversed by waves of from 3 to 4 metres in length brains of rabbits were damaged in certain particular ganglion cell groups while others adjoining were unchanged.

Again, Reiter showed that, when inoculating cases of sarcoma in rats the tumour cells were destroyed without the surrounding tissues being damaged by the heat. But this was only possible at a wave-length of 3.40 metres: other wave-lengths did not yield a similar result.

These facts make it sufficiently clear that the effects of ultra-short waves are altogether different from those of other types. But it must be remembered that experiments in this direction are only in an initial stage. Investigation on an adequate scale will show in years to come to what extent these specific results are of practical importance. The hope is justified that further experience will reveal more and more indications.

Still another and very promising field which has been recently explored is the treatment of progressive paralysis of the brain, which has been considerably improved by this method.

On the basis of experience gained to date, the question is: what range of indications of short-wave therapy may we consider definitely established? The success of the treatment in cases of acute inflammation of the skin such as furuncles and carbuncles is unchallenged. Here especially the contrast between the effects of ultra-short, short waves, and the long-wave diathermic currents is particularly noticeable. It is well known that diathermic currents often

induce further progress of purulent affections so that generalization and even sepsis may result. In such diseases diathermy therefore never, on any account, must be applied. On the other hand, the effect of short-wave currents in such cases is surprising in its healing power, even on larger furuncles or carbuncles. Where no pus has, as yet, been formed pain and inflammation subside almost invariably after the first application. Frequently complete retrogression and resorption, without any formation of pus, can be achieved. In more advanced cases, several applications will prevent further development and may result in complete healing after a small central necrosis has been formed. Very impressive results have been observed again and again, in the treatment of extensive carbuncles. A few days ago, for instance, I was able to effect painlessness after an application of 15 minutes on a carbuncle in process of formation on the thigh of a patient. It had already infiltrated the tissue around across a diameter of 4 inches. The next day, immediately after a second application, a small slough came out and the carbuncle receded and healed. Had it been treated surgically two or three weeks would have been necessary for a complete cure.

Not only in the case of furuncles or carbuncles but also in cases of whitlows and especially of pus formation in the ear, which is extremely painful, I have achieved freedom from pain and retrogression in many cases. Frequently, only one application was needed for this purpose. The same applies even to extensive phlegmonous processes, erysipelas and purulent infiltrations in the subcutaneous tissue, including that of the mammae.

A further most important and especially successful field for treatment by ultra-short waves is that of purulent inflammations of the sinuses of the nasal cavity. The unbearable headache caused by acute inflammation of the frontal sinus decreases in intensity, as a rule after the first application. Usually after 3 to 6 applications the disease is cured. Formerly a large percentage of cases could only be treated surgically. To-day this simple treatment cures almost with certainty even sub-acute or chronic cases. Here again the contrast in the indication of treatment by diathermy must be noted. In these diseases also treatment by diathermy is strongly contra-indicated. In this connection a most instructive case was observed: the patient, before consulting me, had been treated diathermically for inflammation of the right frontal sinus. After two diathermic applications the pain increased so greatly each time that he refused diathermic treatment. Immediately after the first application of short-wave treatment there was considerable improvement and after four further applications the patient was discharged completely cured.

Short-wave treatment is not, however, restricted to the above-mentioned affections. It

acts similarly on acute inflammatory changes of almost every organ, especially in diseases of the roots of the teeth, tonsils, prostate, joints, bones and also those of the female organs.

In an exceedingly painful case of acute gonorrhoeic arthritis of the left wrist, I personally observed how the pain almost completely subsided after the first application. All the symptoms of the disease completely disappeared after a few more applications. A case of a female patient of about 30 years of age was specially remarkable. For ten days she had suffered from severe tonsillitis with a temperature which daily rose to 103°F. During the days preceding the first application, a big swelling of the glands had formed on the left side of her neck. This threatened to become purulent. A few hours after the first application her temperature fell to normal, while on the next day pus was no longer visible on the tonsils and the swelling of the glands had diminished to less than half. After the second application the swelling of the glands completely disappeared and the patient was cured.

Although I had previously no opportunity of observing cases of osteomyelitis I treated a case of otitis media with initial suppuration of the mastoid. Ordinarily, most probably, this would have needed operation. After a daily application for a week there was no discharge and no further pain and the patient was discharged.

It has been shown that the field of indications for treatment by electric currents in acute diseases as described above is altogether new. The success in many of these is actually surprising. Moreover there are very good prospects for short-wave treatment of cases hitherto allocated to the field of diathermy. Nevertheless it must be frankly admitted that in such cases success is not always convincing. Some, like Stieböck, reject even short-wave therapy. Schliephake considers the treatment of chronic arthritis by short waves as a very favourable indication. It must be understood, however, that fixations, already formed, and also osteophytes, cannot be made to recede. From my personal experience I have proved that short-wave therapy succeeds much quicker than diathermy in removing effusions of the joints and pain, even in cases of long standing which have resulted in grave radiological changes. It goes without saying that such cases cannot be cured and that relapses are possible. Still, a lessening of the pains in the joints considerably greater than that achieved by diathermy can be effected.

Success in the treatment of muscular rheumatism and neuritis is even less satisfactory. My experience in this field does not indicate any considerable advance upon previous methods.

But in treating chronic diseases of the abdominal organs surprising success may be achieved. A patient who had suffered for years from a gastric ulcer, radiologically proved, and who

had had an operation upon his gall-bladder and appendix on account of the pain he had suffered for 20 years, was cured after a few applications. At the present moment it is impossible to judge how long this success may last. Still, for the last five months the patient has had no pain whatsoever, whereas for the previous 20 years he had never been free from pain for anything like such a long period.

A further case was one of chronic gastritis with large radiologically-proved adhesions after a very severe appendectomy with peritonitis. For years there had been regular and severe vomiting every morning after getting up. In this case, too, entire freedom from the complaints was established after a few applications. The result was the same in a similar case of severe gastritis and peri-gastritis after operation.

On several occasions, moreover, I observed in cases of gynaecological applications that a discharge due to various causes stopped immediately after the first application and did not reappear during the period of treatment.

Afterwards the discharge began again to a considerably smaller extent. This I would attribute to an unspecific influence on the mucous membrane concerned.

The above enumeration of indications of short-wave therapy cannot claim to be exhaustive. At the present stage it is scarcely possible to be definite regarding the indications. We have also to admit that even the most experienced authorities on this subject are yet of different opinions. It is even not yet generally agreed whether the effects are definitely specific. It has been my endeavour to show that it is unanimously admitted that to-day short-wave treatment has considerably enlarged the scope of the field of electric therapy.

Success has been achieved where but a short time ago it seemed scarcely possible. Continued and varied experience will undoubtedly produce further new indications. To-day we are fully justified in assuming that the study of the effect of particular wave-lengths, which has only just begun, will lead to further results of great therapeutic value.

Medical News

BOMBAY MEDICAL COUNCIL

THE following extracts from a summary of the proceedings of the meeting of the Bombay Medical Council held on 10th February, 1936, are published for information:—

Before commencing the programme of business fixed for the meeting, the President moved the following resolution from the Chair:—

‘That this meeting of members of the Bombay Medical Council assembled on 10th February, 1936, places on record its great sense of sorrow in the death of His Majesty King George V and tenders its respectful sympathy to His Majesty King Edward VIII and Her Majesty Queen Mary;

‘That a copy of the above resolution be forwarded to His Excellency the Governor of Bombay’.

The resolution was carried, all members standing.

The Council proceeded to consider the application from the Director, School of Tropical Medicine, Calcutta, for the recognition of the License in Tropical Medicine of the School for registration as an additional qualification under the Bombay Medical Act, 1912, and decided that the License be recognized for registration accordingly.

The Council proceeded to consider the papers received from Government, relating to the application of Mr. K. A. Nanavutty for permission to be registered under section 7 (3) of the Bombay Medical Act, 1912, and decided that the case be referred back to the executive committee for reconsideration in view of certain further information furnished by him since the matter was dealt with by the committee on the last occasion.

The Council proceeded to consider further the application from the Director, Medical and Sanitation Department, H. E. H. the Nizam's Dominions, for the acceptance of the M.B.B.S. degree and the L.M. & S. diploma of the Osmania University, Hyderabad, Deccan, for registration under the Bombay Medical Act, 1912, and decided that Government be asked to add the two qualifications in question to paragraph 1 of the Schedule to the Act.

The Council proceeded to consider further the application of Mr. M. T. Ramchandani, M.B.B.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register.

The Council proceeded to consider further the application of Mr. N. K. Panse, L.C.P.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register.

The Council proceeded to consider further the application of Mr. G. S. Kasyapi, L.M. & S., for the restoration of his name to the Bombay Medical Register and resolved that some more time should elapse before Mr. Kasyapi's application is entertained.

The Council proceeded to consider the draft rules recommended by the executive committee in connection with the proposed provident fund for the staff of the Council and resolved that the rules, with a few amendments, be adopted and the necessary further steps taken for the institution of the fund.

The Council proceeded to consider the draft revised Code of Medical Ethics prepared by the sub-committee appointed by the Council for the purpose and proposed by the executive committee to be substituted for the existing ‘Warning Notice’ and the ‘Code of Medical Ethics’ and it was resolved that the draft revised code be referred back to the executive committee with a suggestion that it be published first in the *Government Gazette*, the journals of medical associations, etc., with a view to obtain the views of registered medical practitioners.

The Council proceeded to consider a proposal suggesting the institution of legislative control over nursing homes, etc., and resolved that the attention of Government be drawn to the need for legislative control over nursing homes, the numbers of which are increasing in all large cities, and that it be recommended to Government that legislation for the registration and inspection of the same is desirable.

The Council proceeded to record the reply received from the Government of India, in connection with the suggestion received some time ago that the practice

of medicine and dentistry in India be restricted to the nationals of India, *viz.*, that the Government of India do not consider that the situation created by the arrival of a few foreign doctors in this country calls for any action on their part.

The Council decided to record the reply received from the Government of Bombay, in connection with the amendments in the Bombay Medical Act proposed by the Council, *viz.*, that the Governor in Council regrets that he is unable to approve of the proposed amendments.

The Council proceeded to consider the question of appointment of visitors to visit the professional examinations in accordance with rule 110 of the rules of the Council and decided that the Council need not appoint any visitors during 1936, as some time should be allowed for dealing with the points raised by the visitors appointed in 1934.

The Council proceeded to ballot for the election of an executive committee for the year and, in accordance with the result of the ballot, declared the following six members as duly elected:—

Dr. D. A. D'Monte, Dr. Rajabally V. Patel, Sir Mangaldas V. Mehta, The Hon'ble Khan Bahadur Sir Nasarvanji Choksy, Lieut.-Col. Sir Jamshedji N. Duggan, and Lieut.-Col. R. H. Candy, I.M.S.

The Council proceeded to consider the question forwarded by the Chairman, King George Thanksgiving (Anti-Tuberculosis) Fund, regarding the constitution of the Fund, more particularly the relations of that body with the Indian Red Cross Society, and decided that, in the opinion of the Council, out of the three alternatives mentioned, the alternative, 'To approach His Excellency the Viceroy with a recommendation that in future the Thanksgiving Fund be not a sub-committee of the Red Cross, but a separate body to be affiliated to the Red Cross in accordance with section 9 of Act XV of 1920, which constitutes the Indian Red Cross Society', is preferable.

The Council decided to record the reply received from the College of Physicians and Surgeons of Bombay, regarding the reports submitted by the visitors appointed by the Council to visit professional examinations in 1934.

The Council proceeded to consider the question of selection of a representative of the Council, in accordance with a resolution of the Bombay Government, on the committee appointed by Government to examine the problem of teaching at the medical schools in the Presidency, and selected Sir Mangaldas V. Mehta to work as their representative on the committee.

The Council proceeded to consider the motion made by Mr. Amesur, in accordance with a notice given by him, suggesting that as 'Government have declared it as their policy to help towards the gradual development of local self-governing institutions in the provinces of India and to gradually reduce the external control so as to give them the largest measure of independence as is compatible with the due discharge of their duties, etc., etc., the Council request the Governor in Council to reconsider its decision and sanction the proposals (regarding the amendment of the Bombay Medical Act, 1912) forwarded by this Council', but the motion was *lost*, the majority of the members voting against it.

ANNOUNCEMENT OF THE FRANCIS AMORY SEPTENNIAL PRIZE OF THE AMERICAN ACADEMY OF ARTS AND SCIENCES UNDER THE WILL OF FRANCIS AMORY

In compliance with the requirements of a gift under the will of the late Francis Amory of Beverly, Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs, to be known as the Francis Amory Septennial Prize. The gift provides a fund, the income of which may be awarded for conspicuously meritorious contributions to

the field of knowledge 'during the said septennial period next preceding any award thereof, through experiment, study or otherwise.....in the diseases of the human sexual generative organs in general'. The prize may be awarded to any individual or individuals for work of 'extraordinary or exceptional merit' in this field.

In case there is work of a quality to warrant it, the first award will be made in 1940. The total amount of the award will exceed ten thousand dollars, and may be given in one or more awards. It rests solely within the discretion of the Academy whether an award shall be made at the end of any given seven-year period, and also whether on any occasion the prize shall be awarded to more than a single individual.

While there will be no formal nominations, and no formal essays or treatises will be required, the Committee invites suggestions, which should be made to the Amory Fund Committee, care of the American Academy of Arts and Sciences, 28, Newbury Street, Boston, Massachusetts, U. S. A.

RESEARCH STUDY CLUB OF LOS ANGELES

LIEUTENANT-COLONEL ROBERT E. WRIGHT, C.I.E., I.M.S., Superintendent, Government Ophthalmic Hospital, and Professor of Ophthalmology, Medical College, Madras, was invited and accepted an invitation to be the guest of the Research Study Club of Los Angeles, Southern California, U. S. A.

He delivered a course of lectures and practical demonstrations on cataract, glaucoma, orbital tumours, trachoma, superficial punctate keratitis and keratoplasty.

He left Madras on the 8th of December and returned on the 20th of March. Colonel Wright is at present President of the All-India Ophthalmic Society, and is one of the British Representatives on the International Council of Ophthalmology.

INDIAN MEDICAL COUNCIL

LIEUTENANT-COLONEL C. NEWCOMB, B.Ch., D.M. (Oxon.), F.I.C., M.R.C.S., I.M.S., Officiating Surgeon-General with the Government of Madras, has been duly nominated by the Government of Madras under clause (a) of sub-section (1) of section 3 of the Indian Medical Council Act, 1933 (XXVII of 1933), as a member of the Medical Council of India, *vice* Major-General Sir F. P. Connor, Kt., D.S.O., F.R.C.S., D.T.M. & H. (Eng.), L.R.C.P. (Lond.), K.H.S., I.M.S., resigned.

The Use and Abuse of Insulin

By R. D. LAWRENCE, M.D., F.R.C.P.

(From the *Medical Press and Circular*, Vol. CXCII, 1st January, 1936, p. 10)

INSULIN was discovered fourteen years ago and has been increasingly widely used for twelve years. And yet, although thousands of papers have been published on the physiological action and therapeutic use of this pancreatic hormone, the exact mode of its action is not known, nor the extent of its usefulness fully defined. Therefore, although insulin is an old story and thousands of diabetics have now lived on it for ten years, it is not a settled problem—if there is such a thing in medicine—and its use and abuse certainly merits discussion by such a society as ours.

In opening this discussion I am sure the first essential is to try to define in practical terms the physiological action of insulin so as to put the discussion on sure grounds. This can be seen most clearly in diabetes, where injections of insulin remove completely, though

had had an operation upon his gall-bladder and appendix on account of the pain he had suffered for 20 years, was cured after a few applications. At the present moment it is impossible to judge how long this success may last. Still, for the last five months the patient has had no pain whatsoever, whereas for the previous 20 years he had never been free from pain for anything like such a long period.

A further case was one of chronic gastritis with large radiologically-proved adhesions after a very severe appendectomy with peritonitis. For years there had been regular and severe vomiting every morning after getting up. In this case, too, entire freedom from the complaints was established after a few applications. The result was the same in a similar case of severe gastritis and peri-gastritis after operation.

On several occasions, moreover, I observed in cases of gynaecological applications that a discharge due to various causes stopped immediately after the first application and did not reappear during the period of treatment.

Afterwards the discharge began again to a considerably smaller extent. This I would attribute to an unspecific influence on the mucous membrane concerned.

The above enumeration of indications of short-wave therapy cannot claim to be exhaustive. At the present stage it is scarcely possible to be definite regarding the indications. We have also to admit that even the most experienced authorities on this subject are yet of different opinions. It is even not yet generally agreed whether the effects are definitely specific. It has been my endeavour to show that it is unanimously admitted that to-day short-wave treatment has considerably enlarged the scope of the field of electric therapy.

Success has been achieved where but a short time ago it seemed scarcely possible. Continued and varied experience will undoubtedly produce further new indications. To-day we are fully justified in assuming that the study of the effect of particular wave-lengths, which has only just begun, will lead to further results of great therapeutic value.

Medical News

BOMBAY MEDICAL COUNCIL

THE following extracts from a summary of the proceedings of the meeting of the Bombay Medical Council held on 10th February, 1936, are published for information:—

Before commencing the programme of business fixed for the meeting, the President moved the following resolution from the Chair:—

'That this meeting of members of the Bombay Medical Council assembled on 10th February, 1936, places on record its great sense of sorrow in the death of His Majesty King George V and tenders its respectful sympathy to His Majesty King Edward VIII and Her Majesty Queen Mary;

'That a copy of the above resolution be forwarded to His Excellency the Governor of Bombay'.

The resolution was carried, all members standing.

The Council proceeded to consider the application from the Director, School of Tropical Medicine, Calcutta, for the recognition of the License in Tropical Medicine of the School for registration as an additional qualification under the Bombay Medical Act, 1912, and decided that the License be recognized for registration accordingly.

The Council proceeded to consider the papers received from Government, relating to the application of Mr. K. A. Nanavutty for permission to be registered under section 7 (3) of the Bombay Medical Act, 1912, and decided that the case be referred back to the executive committee for reconsideration in view of certain further information furnished by him since the matter was dealt with by the committee on the last occasion.

The Council proceeded to consider further the application from the Director, Medical and Sanitation Department, H. E. H. the Nizam's Dominions, for the acceptance of the M.B.B.S. degree and the L.M. & S. diploma of the Osmania University, Hyderabad, Deccan, for registration under the Bombay Medical Act, 1912, and decided that Government be asked to add the two qualifications in question to paragraph 1 of the Schedule to the Act.

The Council proceeded to consider further the application of Mr. M. T. Ramchandani, M.B.B.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register.

The Council proceeded to consider further the application of Mr. N. K. Panse, L.C.P.S., for the restoration of his name to the Bombay Medical Register and resolved that his name be restored to the Register.

The Council proceeded to consider further the application of Mr. G. S. Kasyapi, L.M. & S., for the restoration of his name to the Bombay Medical Register and resolved that some more time should elapse before Mr. Kasyapi's application is entertained.

The Council proceeded to consider the draft rules recommended by the executive committee in connection with the proposed provident fund for the staff of the Council and resolved that the rules, with a few amendments, be adopted and the necessary further steps taken for the institution of the fund.

The Council proceeded to consider the draft revised Code of Medical Ethics prepared by the sub-committee appointed by the Council for the purpose and proposed by the executive committee to be substituted for the existing 'Warning Notice' and the 'Code of Medical Ethics' and it was resolved that the draft revised code be referred back to the executive committee with a suggestion that it be published first in the *Government Gazette*, the journals of medical associations, etc., with a view to obtain the views of registered medical practitioners.

The Council proceeded to consider a proposal suggesting the institution of legislative control over nursing homes, etc., and resolved that the attention of Government be drawn to the need for legislative control over nursing homes, the numbers of which are increasing in all large cities, and that it be recommended to Government that legislation for the registration and inspection of the same is desirable.

The Council proceeded to record the reply received from the Government of India, in connection with the suggestion received some time ago that the practice

of medicine and dentistry in India be restricted to the nationals of India, *viz.*, that the Government of India do not consider that the situation created by the arrival of a few foreign doctors in this country calls for any action on their part.

The Council decided to record the reply received from the Government of Bombay, in connection with the amendments in the Bombay Medical Act proposed by the Council, *viz.*, that the Governor in Council regrets that he is unable to approve of the proposed amendments.

The Council proceeded to consider the question of appointment of visitors to visit the professional examinations in accordance with rule 110 of the rules of the Council and decided that the Council need not appoint any visitors during 1936, as some time should be allowed for dealing with the points raised by the visitors appointed in 1934.

The Council proceeded to ballot for the election of an executive committee for the year and, in accordance with the result of the ballot, declared the following six members as duly elected:—

Dr. D. A. D'Monte, Dr. Rajabally V. Patel, Sir Mangaldas V. Mehta, The Hon'ble Khan Bahadur Sir Nasarvanji Choksy, Lieut.-Col. Sir Jamshedji N. Duggan, and Lieut.-Col. R. H. Candy, I.M.S.

The Council proceeded to consider the question forwarded by the Chairman, King George Thanksgiving (Anti-Tuberculosis) Fund, regarding the constitution of the Fund, more particularly the relations of that body with the Indian Red Cross Society, and decided that, in the opinion of the Council, out of the three alternatives mentioned, the alternative, 'To approach His Excellency the Viceroy with a recommendation that in future the Thanksgiving Fund be not a sub-committee of the Red Cross, but a separate body to be affiliated to the Red Cross in accordance with section 9 of Act XV of 1920, which constitutes the Indian Red Cross Society', is preferable.

The Council decided to record the reply received from the College of Physicians and Surgeons of Bombay, regarding the reports submitted by the visitors appointed by the Council to visit professional examinations in 1934.

The Council proceeded to consider the question of selection of a representative of the Council, in accordance with a resolution of the Bombay Government, on the committee appointed by Government to examine the problem of teaching at the medical schools in the Presidency, and selected Sir Mangaldas V. Mehta to work as their representative on the committee.

The Council proceeded to consider the motion made by Mr. Amesur, in accordance with a notice given by him, suggesting that as 'Government have declared it as their policy to help towards the gradual development of local self-governing institutions in the provinces of India and to gradually reduce the external control so as to give them the largest measure of independence as is compatible with the due discharge of their duties, etc., etc., the Council request the Governor in Council to reconsider its decision and sanction the proposals (regarding the amendment of the Bombay Medical Act, 1912) forwarded by this Council', but the motion was *lost*, the majority of the members voting against it.

The Use and Abuse of Insulin

By R. D. LAWRENCE, M.D., F.R.C.P.

(From the *Medical Press and Circular*, Vol. CXCII, 1st January, 1936, p. 10)

INSULIN was discovered fourteen years ago and has been increasingly widely used for twelve years. And yet, although thousands of papers have been published on the physiological action and therapeutic use of this pancreatic hormone, the exact mode of its action is not known, nor the extent of its usefulness fully defined. Therefore, although insulin is an old story and thousands of diabetics have now lived on it for ten years, it is not a settled problem—if there is such a thing in medicine—and its use and abuse certainly merits discussion by such a society as ours.

In opening this discussion I am sure the first essential is to try to define in practical terms the physiological action of insulin so as to put the discussion on sure grounds. This can be seen most clearly in diabetes, where injections of insulin remove completely, though

unfortunately only for a short time, all the metabolic defects. These defects consist essentially in a failure to burn and store carbohydrate food (glucose) in the tissues, with resulting hyperglycæmia and glycosuria, and a concomitant failure to metabolize fats, which shows itself in a progressively severe production and excretion of acetone bodies (ketosis) as the carbohydrate burning (the carbohydrate tolerance) becomes less. An injection of insulin, if a large one, abolishes this diabetic process in a few hours. It reduces the blood sugar, it refills the depleted glycogen stores in the liver, less noticeably in the muscles, and when this is done it produces *pari passu* the disappearance of ketosis. The diabetic metabolism is temporarily normal. The exact chemical step it performs in the diabetic defect is not known, but although its effects are widespread, I think it probably only performs one step in the complexity of carbohydrate chemistry.

Another aspect to be considered is the action of insulin on the blood sugar and carbohydrate metabolism of non-diabetics, because they are many non-diabetic conditions in which the use of insulin has been advocated.

When insulin is injected into normals, the blood sugar is always lowered and definite hypoglycæmia is produced if enough is given. Ten units produce appreciable symptoms of hypoglycæmia in most normals when given fasting, fifteen in all, and twenty units quite severe symptoms, usually in two hours. This can always be prevented by the giving of carbohydrate by mouth to balance it. The symptoms of hypoglycæmia are much the same as in diabetes: weakness, tremors, sweating, but hunger is a very common and marked symptom which has been turned to clinical use in stimulating appetite.

There is no evidence that the giving of insulin to non-diabetics increases or affects their metabolism in any specific way, or, indeed, acts as a general tonic. They have already enough insulin of their own.

Another point to mention is that on the current view of insulin production and action, the giving of carbohydrate, usually as glucose, always produces enough insulin to 'look after' the glucose and that the administration of insulin with the glucose is unnecessary to ensure the latter's metabolism. There may be an advantage in adding insulin to glucose in severely ketosed and toxic patients whose production of insulin (to use the current phraseology) may be depressed. But it should be remembered that the giving of insulin alone to such patients with normal blood sugar will not reduce ketosis and is certain to produce symptoms of hypoglycæmia.

I hope this short outline of the physiological action of insulin will enable us to appreciate its use and abuse, both in diabetes and non-diabetic conditions.

Diabetes mellitus is the main indication for the use of insulin. It should be used whenever the utilization of carbohydrate by the diabetic is insufficient to maintain the weight, health and energy necessary for the demands of life, as shown by the persistence of glycosuria, ketonuria and ill-health symptoms in diabetics on restricted diet. It is essential in the treatment of coma and for the continuous welfare of most cases under forty, and in all children diabetics. Many mild cases of diabetes, mostly elderly, do not need it, but most would benefit and would be safer from complications with it; and its use where it is not strictly necessary cannot be termed an abuse—unless it is psychologically harmful. It may be essential, too, to steer quite mild diabetics through the temporary rocks of illness or operation, which makes diabetes worse.

Its chief use is, therefore, to metabolize an adequate diet for the patient's welfare by which he can and should be maintained in normal health, unless other complicating disease is present. I take it, therefore, that unless insulin is producing this happy result it is at least being misused (improperly used) if not abused (wrongly used).

The main difficulty which leads frequently to misuse is the fact that the action of insulin is *quantitative*,

and that patients on the same diet require widely different doses of insulin to control the diabetes and to keep them well. This is not the place to discuss details about diabetic diets, nor what is the best level of carbohydrate, protein and fat, nor total calories, for the diabetic to live with. Some require only 10 units a day, others over 100, and perhaps an average dose in long-standing cases is 40 to 70 units. The commonest error is to give too little insulin—in such insufficient doses that heavy glycosuria and ketonuria persist and the patient derives little real benefit from the daily injections. Equally unfortunate is the patient who is given too much insulin, and is frequently made wretched by hypoglycæmic symptoms. The dose of insulin is always an individual one which must be worked out individually to get the best results and keep the diabetic metabolism as normal as possible. Another difficulty is the necessity of varying most people's dosage from time to time. If these adjustments are not made, a serious misuse of insulin will arise to the detriment of the patient.

It is worth considering the use of insulin in diabetics who, from carelessness with diet, or the irregular necessity of their life, make it quite impossible to control their diabetes at all completely. In other words, they are usually loaded with an excess of sugar both in the blood and urine, if an attempt is made to control their diabetes more completely with large doses of insulin when they eat less carbohydrate than usual. If in these cases two fairly large doses of insulin (20 to 30 units) are given twice a day, such doses metabolize enough carbohydrate to keep ketosis away and to maintain the patient in tolerably good health. Minor symptoms of diabetes—some thirst and polyuria—will be present off and on, but weight and energy will be maintained in spite of heavy glycosuria. Some clinicians are content to use insulin in this way, and it is certainly better to do so than not to prescribe it at all in careless patients. But it is certainly unphysiological to live with a blood sugar from two to four times the normal; the diabetes quickly becomes maximal, and I believe these patients are much more liable to eye and other complications than those who are better controlled.

A serious abuse of insulin in diabetes was prevalent, especially in France, but I hope is now dying out. The method was to give short intensive courses of insulin injections for two to four weeks and then to stop it. These cases, if at all severe, were rapidly improved in strength and weight, but deteriorated again almost as quickly when insulin was withheld. Indeed, there was risk of coma when the treatment was interrupted, a risk which is always present in severe cases (40 to 60 units a day) when insulin is stopped. When we remember that the action of the largest dose of insulin never lasts for more than twelve hours, it is obvious that such intermittent administration can never be successful in maintaining good health in severe cases. It does not mean, however, that milder cases may not come off insulin, and everyone with much experience will agree that insulin may often improve diabetes so much that injections can be given up. The true use of insulin in diabetes can be summed up as the administration of enough insulin to metabolize sufficient carbohydrate to maintain health and strength, a balance of diet and insulin. The main abuses arise from a failure to appreciate its quantitative and short-lived action.

When we pass to the use of insulin in non-diabetic conditions, I feel that we are on more uncertain and insecure ground. It has been recommended in a legion of diseases, and one gets the impression that it has often been used merely because it has such marvellous effects in diabetes that there has been the tendency to 'try it on other metabolic dogs'. When we remember that normal individuals produce sufficient insulin of their own when carbohydrate is administered, we must be sceptical about the effect of adding small doses of insulin to large amounts of sugar. I shall now consider some of the conditions, metabolic and others, in which insulin has been advocated.

One of its earliest non-diabetic uses was to *fatten the thin*, to combat *anorexias* and to prevent *vomiting*, all of which we may consider together. A large literature grew up, especially in Germany, over 'maskuren' with insulin, and in most cases it appeared possible to increase weight with liberal diets and two to three injections of insulin a day, from 5 to 20 units, given before meals. Sometimes this weight was retained when the insulin was stopped and sometimes lost. Some thin people failed to respond altogether, and the treatment has not been universally adopted; and certainly claims that insulin is a general metabolic tonic in normal people have never been scientifically established. It is doubtful if insulin injections can make normal individuals utilize their carbohydrate any better because they produce a sufficiency of their own. But one thing that insulin can often do is to promote appetite and even cause intense hunger when enough is given to produce mild hypoglycæmia, which may force the anorexic patient to eat. Hypoglycæmia occurs in normals some 30 to 45 minutes after an injection, or some two to three hours after a buffering meal. To get the best effect on appetite, therefore, time should be given between the injection and the meal for the blood sugar to drop a little, and another feed of carbohydrate must be given two to three hours later to prevent unpleasant hypoglycæmia. In nervous anorexias, of course, the psychological effect of two to three needle pricks a day may be an important factor *per se* in producing a healthy attitude towards food. Insulin has been widely used in tuberculosis, and good results both on appetite and weight have been published.

A very legitimate use for insulin is in any condition of undernutrition or prolonged vomiting in pregnancy or after anaesthetics which has produced a heavy *ketosis*. Here a vicious circle of vomiting and ketosis is present, and although the giving of carbohydrate, especially glucose, would slowly remove the ketosis the organism is not able to produce insulin or metabolize carbohydrate very readily. The administration of 10 to 15 units of insulin with each 50 grams of glucose will remove the acetone bodies more quickly. Again, it should be remembered that more carbohydrate must be given some three hours after the insulin, otherwise hypoglycæmia will result.

Insulin has been, and still is, used in other metabolic diseases, particularly Graves' disease. This is a catabolic disorder with overactivity of the sympathetic system, which insulin with its anabolic and parasympathetic action might reasonably be expected to antagonize. I made this deduction myself and was probably the first to try it in this country. It is usually possible to fatten these patients with insulin and perhaps to make them stronger for operation. But in my experience I think it has no fundamental effect on the hyperthyroid process and is futile compared with iodine medication.

Insulin has been used in pituitary cachexia (Simmonds' disease) but I have no experience of this.

Again, insulin has been advocated in all sorts of toxæmias and septic conditions, from puerperal sepsis to the toxæmia of diphtheria, and a section of my card-index system is overflowing with those (unread). It will be noticed that in all such conditions it is a question of giving a little insulin with much glucose, and the injected insulin often gets the credit due to the valuable sugar food.

It is convenient to consider the effect of insulin on the diabetic and normal heart together. It is well known that the glycogen content of the diabetic heart, unlike the liver and skeletal muscle, is not reduced and is usually actually increased above normal. This shows that the carbohydrate metabolism of the heart is not dependent on insulin for glycogen formation, but it is equally certain that the diabetic heart utilizes much more glucose when insulin is given. Some reliable recent experiments showed that the increased use of sugar was fourfold after insulin. Clinical experience bears this out, and it is remarkable how much the heart efficiency often improves when insulin is given to

diabetics. On the other hand, partial heart failure and anginal attacks have sometimes been induced in myocardial and vascular degeneration when the sugar content of the blood is too quickly reduced by insulin. One must conclude that such hearts have been accustomed to function their best for years with a high concentration of sugar in the blood and miss its reduction even to normal figures. Hypoglycæmia produces changes in the electrocardiogram in both normals and diabetics, changes which may persist for some time after the blood sugar has been raised. But these hearts benefit enormously from insulin continuously used. It should be mentioned that Lovatt Evans and fellow workers have recently suggested a glucose-lactic-acid system of carbohydrate utilization by the heart apart from glycogen, and it may be that efficiency of this system is upset when the glucose is suddenly reduced by insulin.

In myocardial degeneration in normal individuals, glucose and insulin have been, and are, largely advocated as increasing the efficiency of the heart muscle. On physiological grounds I can see reason for giving glucose, but none for insulin, but hope to hear the opinion and experience of cardiologists on this point.

It will surprise many of you to hear of the number of other conditions for which insulin has been recommended, supported in all seriousness by publication of a few good results: Peptic ulcers, skin ulcer treated by local application, asthma cured by glucose and insulin, cancerous processes improved, morphine addicts helped, and I could mention many more. I have no experience of these, and look upon the claims as fantastic and the methods a serious abuse of insulin.

To sum up, I should say that the chief use of insulin is to maintain life and health in severe diabetics who cannot tolerate adequate diets without it, and this involves its continuous use. It must also be given temporarily to improve milder cases and to steer them past complicating illnesses or operations. In normal individuals its clearest indication is to aid in the removal of ketosis by giving it with carbohydrate, and to stimulate appetite and hunger by causing mild hypoglycæmia.

Investigations on the Outlook on the Diabetic Life

By PROFESSOR DR. W. FALTA

Head of the Medicine Department of the Kaiserine Elezebeth Spital, Vienna

(Translated from the German manuscript by Rai Bahadur Dr. Shiam Manohar Lal. The paper appears in a slightly different form, in the *Wiener Medizinische Wochenschrift*, Jahrg. 83, 25th November, 1933, p. 1337)

It is now generally accepted that diabetes is constantly on the increase specially among cultured people. In India also, diabetes is very common among the educated and many eminent Indians have lost their useful lives either directly or indirectly through diabetes. It has been established by statistics that diabetes has increased from nearly 0.5 to about 1.5 per thousand among the Germans, Swedes, Dutch and other races allied to them. And also, the proportion of diabetic patients as compared with other patients has considerably increased in the larger hospitals. It is certainly very difficult even on the basis of these statistics to come to a definite conclusion about the increase of diabetes. Should we not rather come to the conclusion that owing to the improvement in doctors' education, owing to the increasing knowledge of the general public and owing to the systematic examination of urine by doctors in schools and insurance companies, diabetes is more often diagnosed now than hitherto. It must be finally remarked that owing to the use of insulin in the treatment of this disease the average life of a diabetic patient has been considerably lengthened with the result

that to-day there are more diabetic patients alive than ever before.

Even if it turns out to be a fact that the increase in the frequency of diabetes is only plausible, nevertheless the fact remains that the recorded number of diabetic patients is shockingly high. Umber estimated their number in Germany to be about twenty thousand in 1916 and Katsch considers them to be about one hundred and fifty thousand in 1934. According to Joslin the number of diabetic patients in the U. S. A. is very high. On account of this great increase of the diabetics in all the countries of the civilized world the problem concerns not only the physician who intervenes by curing and preventing the disease but it also interests the whole world as it has a social aspect possibly associated with inheritance.

This paper is chiefly concerned with the question of the change which the treatment of diabetes by insulin has produced upon the outlook and which consequently has in its turn produced its influence on the general public. In the pre-insulin era the statistics of mortality gave a very unfavourable idea of the average duration of life of the diabetic.

Surely the age of the patient at which diabetes develops in a particular case is of utmost importance.

Joslin's large statistics contain the duration of diabetic lives from the beginning to the end of the disease in 592 patients. I have simplified the statistics and have come to the conclusion that the expectation of life is lessened the earlier the disease breaks out. The average duration of life among diabetics may be regarded as 48 years.

From the statistics of the pre-insulin era we are driven to the conclusion that diabetics mostly died of diabetes. According to van Noorden 25 per cent of the diabetics died of coma; according to Joslin 51 per cent. The diabetics are further prone to tuberculous infection which causes death of some; premature arterio-sclerosis leads to gangrene of which many diabetics die.

One would expect that the prognosis of the diabetics would have so much improved by the discovery of insulin that they would reach the age of a non-diabetic man; so if the hypothesis that the diabetic disturbance of metabolism is a deficiency disease be correct, then we may expect that the defect can be completely met by insulin in the same way as in myxœdema we can relieve the condition by thyroid substance.

It is surprising that large statistics about duration of life and mortality of diabetic patients which have been published after the discovery of insulin in different parts of the world give such a favourable result as we did not expect. Joslin has convincing data to show that the average life of a diabetic patient has increased to 77 years, giving 29 years more for a diabetic to live.

It is also proved by statistics in Germany that deaths from diabetes in hospitals have considerably diminished; only those diabetics die who are not protected by insulin and their working capacity is also relatively small.

Among the higher classes of society the results are still more favourable; while the mortality among the poorer classes was very high according to Reinwein and Parker in the Hospital of Wurzburg, it amounted to only 13.6 per cent among the higher classes. It is also remarkable that death among diabetic children has considerably diminished and according to Joslin and White it is 12 per cent and according to Wanger and Priesel it is only 1 per cent.

From these facts it is abundantly clear that we can form a positive opinion about the utility of insulin not only from statistics but also from our experience of individual cases. Apart from the treatment the result depends also on many other factors such as the peculiarity of the case, complications and systematic regime. The last is influenced by external conditions of life such as psychical condition of the patient and his attitude towards the disease.

II

Let us first of all consider the peculiarities of the case. It is well known that human diabetes appears in manifold forms. Though in the majority of cases the insular organ is diseased, there are other forms in which from development of symptoms we conclude that the endocrine glands (thyroid, hypophysis, suprarenal) are at fault whilst in many other cases the disease is due to defects in the central nervous system. If we do not take into account these relatively rare cases only two forms remain to be considered:—

The one in which the patient continuously loses weight and becomes thin, and the other in which the patient is corpulent and shows little tendency towards losing flesh. It is very interesting that in the ancient books on the Indian system of treatment these two forms were differentiated and mentioned so long ago as six centuries B.C. Professor Wickrama Singh, the Sanskrit scholar, called my attention to a work by T. A. Wise published in 1845, in which it is shown that the sweet taste of diabetic urine was known to the Indian doctors and they characterize both the forms due to the one fact, *viz*, sweetness in sugar.

In one form the disease is described as congenital in which the patient becomes weak, loses flesh, his skin becomes rough and the patient eats much food, drinks much water and is always restless. In the other form the patient is fat, takes much food, the surface of the body is soft and oily; they are sedentary and sleep much. In the treatment of the first form nourishing food is recommended and for the second form easily digestible food with occasional fasting is recommended. In the year 1877, after two thousand and five hundred years this differential diagnosis was introduced again by M. Laucaran and his pupil Lapierer. They differentiated an acute form which they attributed to diseased pancreas and which they called *diabete maigre* or *diabete pancreatino*; and the other a chronic one affecting fat men which they called *diabete gras*. German Doctors Naunyn and Noorden have used this differentiation.

The characteristic of *diabete gras* is high blood pressure. Hitzberger has been the first to prove by statistics that such is the case and I have also found in my private patients that high blood pressure is more frequent in diabetics than in non-diabetics of the same age. Rschmidt later on put down the behaviour of blood pressure as the chief point in differential diagnosis.

For the differential diagnosis between these two chief forms of diabetes I have found out a new symptom, *viz*, the different sensitiveness towards insulin. I have done this in collaboration with Radoslav, Mpisch, Hogler, Boller, Schwarz and Fenz.

Radoslav has demonstrated by experiments how the reaction to insulin in different cases differs. This difference in the sensitiveness is in proportion to the gravity of the case. It becomes clear by the examination for the deficiency of insulin. This is the quantity of insulin which is necessary to render the patient's urine sugar-free on a fixed diet and to keep him so. Since the introduction of insulin I have estimated this deficiency in about two thousand cases of diabetes and thus I have been able to compare the deficiency of insulin in different cases on the one hand and the amount of insulin which is necessary to keep the patient sugar-free in every individual case on the other hand.

It has been proved from statistics that the want of insulin in different cases differs to an extraordinary degree and that it has no constant ratio as regards the diabetic disturbance of metabolism. For instance one patient with the standard diet excreted about 150 grammes of sugar and needed only about 30 units of insulin to render him sugar-free, whilst in another case, who excreted 150 grammes of sugar, 280 units of insulin were necessary to render the urine sugar-free. If we divide the quantity of sugar excreted by the number of units of insulin to render the individual sugar-free, we get the glucose equivalent (g.e.).

In the first case it is about 5; in the second case it is 0.4. In the course of treatment which lasted through several years it was found clinically that one case was not at all more difficult than the other.

We can fix the g.e. by the experiment of stopping insulin for one day and thus noting the amount of sugar excreted which is in proportion to the insulin-want. This method is specially important in those cases in which we cannot leave the patient for a long time on a fixed diet without incurring the danger of onset of ketosis. Such was actually the case with a patient in whom by stopping insulin symptoms of coma began to appear. This case showed that the g.e. does not go parallel with the severity of the case. It has been urged that the sensitiveness to insulin depends upon so many other factors such as the form of food and complications of infection, that the g.e. cannot be of any value in the differential diagnosis of various forms. I refute this objection. Regarding the food, my patients were all on a fixed diet. As regards infection I have found that they increase the insulin-want and decrease the g.e. Also psychical emotions, anaphylaxis, etc., can influence both the insulin-want and g.e. There is always the question of temporary insulin resistance. When the cause disappears the true character of the special case again comes to light.

I think my statistics are convincing because I have in a large number of cases estimated the insulin-want and the g.e. for many years in a systematic way. In the insulin sensitive case the g.e. is very high already in the initial stages and remains constant and subsequently arises even higher. The g.e. of the insulin resistant cases is small from the beginning and remains so during the whole course. If an infection supervenes the g.e. declines temporarily only in the insulin resistant cases but the differences are never high. It appears that the g.e. increases in the insulin resistant cases which I have observed for 6 to 8 years.

The observations based on quite a large number of cases, therefore, undoubtedly established the fact that sensitiveness to insulin is a peculiarity fixed in the constitution of every individual. Somehow this peculiarity depends upon the age of the individual. Specialists in treating children's diseases also say there is no constant insulin resistance in them; if it is at all found it is temporary. We find the constant insulin resistance only in the middle life and upwards but there are also cases in older people who are evidently insulin sensitive. This variation in the sensitiveness to insulin is directly related to the differential diagnosis of both the forms of diabetes. I have already said that frequently in children and young patients who have a tuberculous tendency the insulin resistance is very small while it is very high in patients of middle age and higher life, in whom, latter, adiposis and hypertony often coexist. The first have a progressive character with some variation; the last show frequently slow progress. It would be quite wrong to record the last cases as benign ones because they can take clearly a progressive character as has been frequently seen.

I should go far if I enter into the question of the pathogenic differences between these two groups. Only in a short way, I will state that insulin sensitive cases are probably insular in origin; though there is, nevertheless, a similarity in pathological anatomy on this point. Mostly the insulin resistant cases show a special constitution and insular preponderance.

III

Now I start with the chief part concerning the course and prognosis and also expectation of life in various diabetic forms. The most favourable cases are those in which the treatment is aetiological because the disease is then completely healed. On this point unfortunately the treatment of the diabetic is still in its initial stage. For the most part the treatment consists in regulating diet and administering insulin. As regards the diabetic treatment, which was available in the pre-insulin era, the results were seldom satisfactory in the

real insular cases though I do not in any way under-value its importance. There are too, as mentioned above, the real insular cases with slow progress in which we can proceed by regulating the diet and for years such cases can be kept in good health and state of nutrition. The course of insular cases was in most cases progressive as the inclination to ketosis was progressive in the days before insulin was discovered. We had to resort to oat-cure (introduced by van Noorden) and the treatment with cereals recommended by many.

By the discovery of insulin the course and prognosis of this group of cases has been much changed; we compensate in the shortest time their diabetic metabolism disturbance and make the patient speedily sugar- and acetone-free, restoring the normal state of nutrition and enabling the muscles to function in a normal condition. Under insulin protection a normal development of young individuals can be obtained. In short such individuals can be made by insulin strong and efficient men with healthy appearance, even though early in their life the disease was progressive. Pregnancy of women can be made not only quite normal but also, it is to be mentioned, that they frequently produce abnormally tall children so that Cæsarean section becomes necessary.

What happens to these cases further on? I have collected a number of cases both from hospital and private practice to show this. Besides the question is of special interest, whether by continuing insulin protection the progress of the disease can be stopped or not. Besides we can find out whether the disease is or is not of the insular organ. Regarding the prognosis of life of the established insular cases, the blessing of the insulin for the diabetics is to be seen in the best light. The same holds for less serious cases for they know for a certainty that they continue their life by insulin protection as soon as it is found out that the mere regulation of diet is not sufficient. Worse cases whose life cannot be prolonged can still be kept in a condition of good health and nutrition with the help of insulin. Their normal capacity and their development can also be kept normal, should the disease start at an early age in childhood. Nevertheless, the experience in such cases till now is not of a longer duration than 12 years, so there is nothing at present against keeping them under the protection of insulin for a longer time.

Such a favourable course unfortunately can be expected only with good life condition and according to the character of the patient himself. The prognosis for life in these cases is very unfavourable. Naturally they desire the restoration to a non-diabetic life. Then the life of such men must have some relation to insulin protection. It may also happen that some accident may make the patient for a short time inaccessible to insulin or hypoglycæmia may set in. By careful watching the hypoglycæmic attacks can be avoided though when the treatment is to be continued for years such a possibility does exist. Such a hypoglycæmia might be fatal to the patient. One of my patients, who was very careful and was splendidly trained, one day swam out in a bathing place too far and did not return any more, as most probably he had had a hypoglycæmic attack.

Do not forget that such individuals should never be regarded as normal and the choice of profession for them should be limited. As hypoglycæmic attacks cannot be avoided, such professions should be closed to them where a hypoglycæmic attack would prove fatal such as the profession of chauffeur, pilot or a mechanical engineer.

Further, useful operations have lost their former danger and complications, of which we were afraid before, can be better met, though there is still some risk of some complications appearing under conditions to which the patient is not adapted, for instance falling ill in foreign countries.

If insulin intoxication be at all a common condition a great experience would be gained and it would be

possible to follow the waves of the blood sugar with insulin and make them correspond with the irregularities such as cannot be avoided in operations. Such mistakes chiefly occur when sufficient stock of glucose has not been provided to the patient by the administration of sugar and insulin. The exact amount of insulin required is often rendered more difficult. Nervous emotions sometimes overthrow the whole elaborate work and in such the danger of bad hypoglycæmic attack is proportionately greater of course.

Now I come to the prognosis of life of the second group of cases which are insulin resistant, that is they are insular in origin having an extra-insular preponderance. I have collected a series of such cases which can be accepted as types of this class.

First I will speak of less serious cases who are fat and have a high blood pressure. The beginning in general is acute. The sugar lessens easily in unprogressive cases either by regulating diet or by regulating high doses of insulin. With insulin, urine becomes sugar-free much more quickly and a higher tolerance of carbohydrates seems to be reached without insulin. Often recovery of an enormous tolerance for food without insulin can be reached, in some cases there are always relapses. In serious cases constant insulin protection from the beginning is required.

In regard to the prognosis of these cases I like to restrict myself shortly to the following points:—

(1) In the majority of cases progress is slow and they take a long time to recover; urine becomes sugar-free with large doses of insulin. Metabolism is enormously improved but relapses are frequent. If continued insulin treatment is necessary then it is very costly on account of high doses of insulin necessary.

(2) In estimating the duration of life one should bear in mind that there is not only diabetes but a adiposity and hypertony to be taken into consideration.

(3) If the disease is long continued, sclerosis is likely to set in. These are the cases in which sooner or later sclerosis of coronary, cerebral, kidney and extremity arteries is liable to develop.

Before I begin with complications I must mention the so-called chronic diabetes in which the progress is extremely slow. In the majority of cases there is sclerosis in the artery of the pancreas which causes mild diabetes. Often sugar disappears without any help for a short or long time or even permanently. Naturally the prognosis for life is greater under favourable expectant treatment.

IV

Complications are of special importance for prognosis. There was always Damocles' sword hanging above their heads before the insulin days. Therefore the outlook was bad, metabolism being in a high degree of instability producing ketosis very often. In chronic cases or in cases with frequent serious relapses they influence the progress unfavourably either on account of the damage to the insular organ by the augmentation of extra-insular factors.

They were more dangerous also because the treatment was more difficult. Many complications such as disturbances of stomach and intestines, kidney diseases, etc., required a diet which was quite opposite to what was suited, for their diabetes, before insulin was discovered. There are two groups of complications of diabetes; one group consists of complications produced by diabetes itself and the other to accidents.

To the first group belong all those conditions of illness in which there is a bad tendency of healing up of tissues and a liability to infections (such as pyorrhœa alveolaris, furunculosis, phlegmon, etc.).

Again, there are complications of nervous system and the skin (pruritus, eczema, etc.), cataract, premature arterio-sclerosis, angina pectoris, contracted kidney, apoplexy, gangrene, etc. Concerning now the purely insular cases, formerly the opinion of the specialists for the diabetes of children was that complications in diabetic children were wanting. There is nothing to record that it was not so. P. White and Joslin found

that out of 87 diabetic children, who fell ill before the discovery of insulin and lived till the year 1931, there were 19 cases (22 per cent) of complication from the diseases of the vessels and two suffered from diabetic cataract.

From this it is evident that the complications which were caused by diabetes were rarely observed in the pre-insulin era in young individuals—such as pyorrhœa alveolaris, pyoderma, etc. It may be that the children did not notice the onset of these complications.

The occurrence of arterio-sclerosis among diabetic patients in comparison with non-diabetic patients is greater in patients of middle and higher ages, and as already said, specially in insulin resistant cases in which premature vascularity and hypertony coexist.

The question whether the tendency of diabetic patients to premature hypertony or arterio-sclerosis or both has changed after the discovery of insulin cannot yet be definitely answered. It is certain that the danger of arterio-sclerosis continues to be great and increases as the age advances. In spite of treatment with insulin death from arterio-sclerosis takes the first place.

Nevertheless, on the contrary we can also assert with confidence that insulin has brought great advantages for the treatment of these complications: specially gangrene which in the majority of cases heals under protection and gives better chances than when an operation was necessary. Joslin also affirms that now gangrene has not the same sad outlook with careful insulin treatment that it had in the pre-insulin days.

It is also important to note that in the case of kidney sclerosis and of essential hypertony we can guide the course of treatment in the diabetics as we can in the non-diabetic cases. I do not agree with those authors who state that angina pectoris is a contraindication for treatment with insulin. Quite on the contrary I have experience that in such cases we are able to nourish the diseased heart muscles by insulin treatment much better and therefore with greater success.

Artificial Pneumothorax for the Relief of Acute Pleural Pain

By C. SHAW, M.B. (Camb.), M.R.C.P. (Lond.)

(Abstracted from the *Lancet*, Vol. II, 7th December, 1935, p. 1280)

SYMPTOMATIC therapy, so often a *faute-de-mieux* resource, acquires a biological significance approaching that of specific therapy, when, by increasing subjective comfort it removes, in addition, a pathogenic factor of potential danger to life. This generalization is aptly exemplified by the successful treatment of pleural pain. In the young and robust, the pain of acute pleural inflammation, because of its agonizing character, demands relief primarily on grounds of humanity. In the middle-aged or elderly, however, the onus of therapeutic responsibility is greatly augmented by the probable occurrence of the serious results which commonly follow upon failure to confer subjective relief; for in such patients myocardial failure and death may be sequelæ of the restlessness, insomnia, and anoxæmia occasioned by the respiratory pain, whilst the shallow, pain-inhibited respiratory excursion produces a varying degree of pulmonary basal atelectasis, which is the prelude to pneumonic infection and its satellite toxæmia with a predilection for the myocardium and the medullary centres.

Ideally, rational symptomatic therapy should achieve alleviation of a symptom by nullification or attenuation of the physio-pathological mechanism basic in its production. Scientific accuracy of this order cannot be claimed in regard to the symptom of pleural pain; neither the popular theory of friction between inflamed serous surfaces, nor Bray's concept of parietal pleural elastic tension, is universally applicable. But there remains the universally accepted clinical observation

that separation of the visceral and parietal pleural layers, whether by fluid or by air, results, without exception, in the disappearance of the pain of acute pleurisy. The methods generally adopted to relieve pleural pain are (1) strapping the affected hemithorax, (2) the application of counter-irritants, and (3) the exhibition of narcotic-analgesic drugs of the opium or barbiturate group. Attempted immobilization by strapping is only partially effective, and has the disadvantage that it favours the production of atelectasis; it also hampers consistent clinical and radiological examination. The application of counter-irritants results chiefly in the greasy discomfort of the clinician in charge of the case. The exhibition of narcotic-analgesic drugs is indictable on their inefficacy except in doses capable of inducing cardiomedullary depression which expedites the initiation of anoxæmia, atelectasis, and their attendant ills.

Because of its acknowledgedly complete efficacy in relieving pleural pain, separation of the pleural layers, as by an artificial pneumothorax, seems to be the most rational mode of therapy; its employment, though generally recognized in textbooks, is mentioned by them only in terms of curt dismissal. The risk of secondary pleural infection, of causing or increasing myocardial distress, and of superimposing the dangers inherent in the induction of pneumothorax—such as pleural shock and air embolism—appear to be the reasons underlying this attitude. They are more theoretical than experimental, and critical examination reveals them as bogies with a very infrequent incidence and therefore of insignificant import when balanced against the prophylactic value of efficiently abolishing the anguish of respiratory pain with its clinical consequences.

Comment.—The two case-histories reported (not included in this abstract) have many common features. In each case the patient was elderly and had developed an atelectatic pneumonia because of the shallow breathing necessitated by the pain of acute pleurisy coupled with compulsory adoption of the supine posture; in one case the correctness of the diagnosis was supported radiologically; in both cases the anoxæmia consequent upon shallow breathing and partial pulmonary atelectasis, added to the toxæmia of secondary pneumonic infection, compelled a prognosis of death from cardiomedullary depression. But in both cases the induction of a shallow pneumothorax produced a dramatic metamorphosis of the clinical and prognostic picture, by its relief of respiratory pain, and so of the anoxæmia and atelectasis; moreover, in each case the amount of air sufficient to give relief was too small (250 c.cm.) to be capable of causing myocardial embarrassment. The employment of artificial pneumothorax for acute dry pleurisy has theoretical sanction because of its accepted efficacy in removing the respiratory pain, especially since it thus minimizes the possible sequential dangers facing the patient. The two cases detailed show that this theoretical sanction is supportable by practical experience.

The general circumstances indicating the therapeutic employment of pneumothorax for pleural pain have been considered. In post-operative cases in which an abdominally initiated diaphragmatic paralysis enhances pulmonary basal atelectasis its value seems worthy of further research. Coghlan in this country and many foreign observers have advocated lung collapse for the treatment of lobar pneumonia; but despite the striking support given to them by the experimental studies of Lieberman and Leopold their advocacy has not found general favour, chiefly because of a theory based on clinical timidity. Whatever the theoretical objections to the induction of major lung collapse in lobar pneumonia, there can be few or none to a consideration of the pain-removing, comfort-giving injection of the innocuously small amount of air necessary to produce pleural separation in those early days of the disease in which the ultimate prognosis is influenced by the degree of general and myocardial exhaustion to which the patient is subjected.

SUMMARY

1. The pain of acute dry pleurisy demands removal in young patients on humane grounds; in the elderly this is imperative as a prophylactic measure against the occurrence of anoxæmia and atelectatic pneumonia which is so often fatal.
2. The therapeutic methods in general use are either only very partially effective or dangerous.
3. The induction of a shallow pneumothorax invariably relieves pleural pain and so removes anoxæmia and atelectasis. The amount of injected air necessary is so small as to be quite harmless.
4. Two cases are detailed in which atelectatic pneumonia and anoxæmia, secondary to pleural pain, suggested a fatal prognosis. Dramatic recovery followed the induction of an analgesic pneumothorax.
5. The indications for the employment of pneumothorax to relieve acute pleural pain are discussed.

Tachycardia

By C. E. K. HERAPATH, M.C., M.D.

(From the *Medical Press and Circular*, Vol. CXCI, 6th November, 1935, p. 406)

TACHYCARDIA is not a disease, but a symptom. In the majority of cases it is a symptom of some alteration of function which calls for an increase of the speed of the circulation. In trained athletes this can be brought about by an increase of the output of the heart per beat; but in the ordinary individual there is an increase of the rate per minute, that is, an increase of the rate of the heart. In a few instances tachycardia is a symptom of some derangement of the heart itself, chiefly some abnormal rhythm. Physiologically the quicker the heart beats the less forcible are the contractions, but some tachycardias are associated with an augmentation or increase in force of the contractions; these cases are not caused by heart disease. Thus the tachycardias may be divided into (1) extra-cardiac cases; (2) cardiac cases.

What are the causes of increase in the rate of the heart? They are very numerous. Anything which stimulates the action of the sympathetic nervous system causes an increase of the pulse rate: thus exercise, emotion, either fear, anger, excitement, or concentrated mental effort, all call for increased outpouring of adrenalin and cause an increase in rate. In the same way fever, increasing metabolism, demands more blood to be supplied to the tissues and thereby calls for an increase in rate of the heart, but we must remember that the morbid process producing the fever may have a toxic effect on the cardiac muscle, and some of the increase in rate may be due to this cause; one must therefore be on the look out for a tachycardia which seems to be in excess of what one would expect with a certain temperature. A good example of this may be seen in lobar pneumonia, where a heart rate of over 120 per minute is a sign of bad omen.

Functional nerve disease is a very common cause of tachycardia, and one which is often very puzzling to the practitioner, but if the individual be considered instead of the heart, other signs will be found which point to the nervous system.

On examination of the heart one finds a widespread cardiac impulse, but the maximum will be found well internal to the mid-clavicular line; a functional tachycardia is usually associated with a small heart. There may be a systolic murmur at the apex but we must be shy of such a murmur unless there be cardiac enlargement. One usually finds that the maximum sound of the murmur is internal to the apex beat, and it is not conducted outwards towards the axilla. It may disappear when one lies the patient down. These little differences show that it is not an organic murmur and is not a sign of valvular disease. Sometimes a murmur is heard only during inspiration and if the breath be held in full inspiration, it disappears. This is a cardio-pulmonary murmur which is caused by a small portion

of lung being compressed by the heart, and some air is expressed every time the heart contracts, making a noise very much the same as a murmur. These cases often complain of a stabbing pain or a dull ache over the whole precordium, and in some cases there may be pain over the heart associated with a pain down the left arm, which makes one consider the diagnosis of angina pectoris. On further inquiry one finds that the pain is not in any way associated with exercise, but is more often brought on by excitement and very frequently occurs in the middle of the night. Such symptoms are mostly met with in young people who are not old enough for angina, for the latter disease does not often arise till middle age has been reached. The heart rate in these functional cases may be anything from 90 to 140, or in a few cases 160, per minute, and it is always regular if the rate is high. On lying them down some slowing is always found; occasionally the rate is markedly slowed and at this time premature contractions or extrasystoles are very likely to occur. On further examination one finds that the arteries are not thickened, but the blood pressure may be on the high side, due to the increase in rate. There will be no albumin in the urine.

These findings suggest that there is no disease in the heart, for even in the presence of shortness of breath and tachycardia, to diagnose heart disease one should find some cardiac enlargement, some definite valvular murmur, some thickening of the arteries or some slight signs of failure such as the veins in the neck standing out and not emptying during diastole when the patient is in the semi-prone position, or some oedema of the feet in the evenings.

If the history of such a case be taken carefully the diagnosis is easy; one finds that they are nervous individuals, frightened of traffic or of crowded places; they sleep badly and sweat a lot, they are irritable and have lost the power of mental concentration; if the pulse be quick they complain of shortness of breath, palpitation and pain in the region of the heart; they show a coarse tremor in the hands and often the tongue, and the knee jerks are exaggerated and often of a multiple nature—a tap may send the whole leg into clonus. The symptoms they complain of are innumerable, and their manner shows an introspective nature; these two facts should always suggest some functional nerve complaint.

These cases are usually convinced that they have heart disease; the rate of the heart, the shortness of breath and the pain all help to convince them of the gravity of their disease, and to the lay mind heart disease means sudden death, or at least a speedy end.

These are the cases we saw so many of at the end of the war, and even now in civil life there are a great number of them, mostly in women, though one sees many such cases in men. Life at present is a very strenuous affair, employment is so precarious and pleasures are taken so seriously that it is easily seen how the nervous system is overtaxed. The first rule of treatment is to try and convince them that the heart is not diseased and is not really at fault; until this has been accomplished no treatment is of any avail, for the idea of heart disease only makes them more anxious and aggravates the symptoms, so that they are in a vicious circle. If they cannot be made to see this clearly it is wise to send them for a second opinion. Confirmation of the diagnosis will often help them to realize that their nervous systems are really at fault.

This disease is often met with after an attack of influenza, which at times has a great depressing action on the nervous system; and it commonly appears after a long and debilitating illness.

The next cause of extra-cardiac tachycardia to be considered is due to thyroid disease, for in the early stages it is very similar to the previous condition. In both there is a normal heart with tachycardia, for although heart disease occurs in the later stages of Graves' disease, the picture will then be so plain that mistakes will not occur. There are little points in the history which will serve to separate the two conditions.

Graves' disease is associated with an augmentation of the beat as well as tachycardia; they complain of violent beating, and cases of this disease are not nearly so often accompanied by pain over the heart. A history of unexplainable attacks of diarrhoea are suggestive of thyroid disease. Wasting is an important symptom, but so it may be in the nervous tachycardia; but the difference is that in Graves' disease the wasting is progressive in spite of the patient eating very good meals, while the nervous cases do not waste unless they do not eat well. The tremor of thyroid disease is very fine and quick, and is best brought out by extending the arms to the full extent with the fingers spread out. The actions and speech of the goitre patients are quick, impulsive and excited, and they are very apt to weep at one moment and laugh at the next moment; another peculiarity of these cases is that they enjoy the coldest weather and never feel the cold, whereas hot weather always makes them worse. Slight enlargement of the thyroid does not help, for the nervous tachycardias are often accompanied with some slight enlargement.

Tachycardia in cardiac disease is mostly caused by the inception of some abnormal rhythm such as auricular fibrillation, auricular flutter or paroxysmal tachycardia, although it may be seen in cases of cardiac failure, where it is the last effort of the heart to keep the circulation up to normal rate. These cases are obvious and do not really need mention. One also sees tachycardia with valvular lesions fairly frequently, but the history shows instability of the nervous system, and these cases are a mixture of organic disease with functional nervous tachycardia superimposed. I often tell my students that the chief use of a cardiologist is to remove the functional element from these cases, when the patients improve to such an extent that they often think that one has cured them of heart disease.

TACHYCARDIA WITH ABNORMAL RHYTHMS

Auricular fibrillation is often seen in rheumatic hearts, thyroid disease, and in individuals who are past middle life and who have arterial disease. It is a condition of inco-ordination of the auricular contraction, and the irregularity is passed, by means of the bundle of His, to the ventricles. The irregularity is one of both rhythm and force, so that no two heart cycles are of the same length, nor is the pressure of the same strength. Though this condition may be met with in slow hearts, the usual type is a tachycardia of anything from 120 to 140 or more. Many of the smaller beats do not reach the pulse at the wrist, so that the pulse is much slower than the real heart rate. This condition is termed pulse deficiency and is useful to confirm the diagnosis. Of course, none of the beats which do not reach the wrist do anything towards helping the circulation, and consequently this condition is very often associated with congestive heart failure. If the heart rate be slowed by digitalis, the ventricles are able to recover their tone and are quite able to carry on the circulation, because when slowing takes place each beat is much stronger, even though the irregularity still remains.

In auricular flutter there is little or no irregularity, but the auricles contract at a rate approximating 300 per minute. This rate is much faster than the average bundle of His can deal with, and one usually finds that every other beat is blocked by the bundle and the pulse rate is about 150 per minute. Sometimes only one beat in four comes through to the ventricles, and the pulse rate is about 75 per minute. Occasionally it is found that on exercise the ventricular rate becomes equal to the auricular rate. I have one electrocardiogram of such a case where on exercise the ventricular rate was 268 per minute, but after a few minutes this was halved to 134, much to the relief of the patient.

This makes it possible to sometimes diagnose the condition clinically, for if a case has a rate of 150, which practically never varies unless it jumps to 75 or to 300, then one would be justified in diagnosing auricular flutter. There is only one other condition where

halving of the pulse rate can occur, and this is where there is a premature beat or extrasystole at every alternate beat, which is not always present; but in this case the sound of the two beats should be heard at the heart, and also premature beats do not usually occur when the ventricles are as quick as 150. It is also sometimes possible to see that the jugular bulb is beating at a rate twice as fast as the ventricular rate.

Paroxysmal tachycardias are rhythmical series of beats which usually approximate to 180 to 200 per minute. They may arise from the auricle, ventricle or from the bundle of His. They are thought to occur in the same way as a premature beat, except that whereas in the premature beat there is only one contraction, in the tachycardia there is a series of them following one after the other. The cause of this might be an irritable focus, but the actual ætiology is unknown.

The length of the attacks varies very much: some may stop in a few minutes, others may go on for hours or days. They usually start early in life, about the age of fifteen to twenty, though sometimes one sees the first attack much later, and they may occur at irregular periods all their lives. In a young healthy person they appear to do little harm, and as soon as the paroxysm stops they carry on with what they were doing when it began; but as life goes on and the myocardium is not so healthy, the attacks upset the patient and may even bring on heart failure of the congestive type, and it may take some time for the patient to recover from them. It might be thought that the attacks will in time become more lengthy, but this does not often happen. The length of the

attacks seem to vary from time to time in quite a haphazard manner. The diagnosis between auricular, ventricular or nodal attacks is of little importance except from a scientific point of view, and can only be distinguished by means of an electrocardiogram; clinically it is not possible to give any opinion. The prognosis is important and a true estimate can only be given by judging the effect of the attack upon the patient, especially noticing the occurrence of cyanosis, dyspnoea, enlargement of the liver or oedema of the ankles. If any of these be present, the prognosis must be guarded, but if the attack causes no sign of failure the prognosis is good. I remember one case where an attack, which was, as far as one could find out, the first one, did not stop, and after six weeks he died of heart failure; this, however, is a very rare occurrence. Various methods of stopping these attacks are mentioned in books, but in reality there is no sure and certain method. Every patient has a story of how he stopped the last attack, but the real truth is that the attack happened to stop when he was doing something, and he naturally thought that this stopped it. One case informed me that the attacks always went on till he vomited, but that this stopped it. I happened later to see him in an attack; he vomited, but the attack still went on. In the same way nothing is known as to what brings on the paroxysm: some blame an excessive exertion, some blame overloading of the stomach, but in reality they may come on at any time, and I have known them to start during sleep.

The diagnosis is very simple: if the tachycardia comes on all of a sudden and stops as suddenly, a diagnosis of paroxysmal tachycardia may confidently be made provided the rate be 180 per minute or more.

Reviews

MODERN TREATMENT IN GENERAL PRACTICE.
VOLUME II.—Edited by C. P. G. Wakeley, D.Sc.,
F.R.C.S., F.R.S.E. Messrs. Butterworth and Com-
pany (India) Limited, Calcutta, Bombay and
Madras. Pp. viii plus 382. Illustrated. Price,
Rs. 7-14

THE *Medical Press and Circular* is in many ways an ideal journal for the general practitioner. There are few numbers of the *Gazette* in which we have not included in our 'current topics' section a lengthy extract from this useful paper. A few years ago the editor started a series entitled 'Modern Treatment in General Practice'; these were deservedly popular, and when the first series of these articles was published in book form a reprint was demanded within six months. The book under review contains a second series of articles on the same lines.

There are forty chapters written by thirty-nine contributors on subjects that are all of great interest to the practitioner; they are written primarily from the point of view of treatment but naturally diagnosis and pathology are considered in so far as they influence the treatment or explain its rationale. The contributors are all recognized authorities on their subjects. The articles are not arranged in any special order but are more or less alternately on medical and surgical subjects. Most of the articles deal with the treatment of some specific condition, such as appendicitis in children and fractures of the patella, but there are also more general chapters, such as on the value of biochemistry—this deals mainly with dietetics—and on physical treatment in general practice.

The first article, by Sir William Wilcox, on gastric and duodenal ulcer was, in the opinion of the reviewer, disappointing, but this was the only one that he found so. In this article the indications given for medical treatment as against surgical are the ones now generally

accepted but the details given for the dietetic treatment are too sketchy and the indications for the adoption of the various procedures suggested are not precise enough; the reviewer has had no experience of the duodenal tube method of treatment but finds here little encouragement to try it, although the writer expresses himself in favour of that form of treatment.

The article on constipation—a very difficult subject—was rational and very helpful. Great emphasis is laid on habit; ninety per cent of constipation is probably due to the failure to adopt good habits in this matter in childhood and early youth. The writer does not tirade against purgatives, as many writers on this subject do, but points out their uses and issues warnings against their abuses.

Pneumonia is also dealt with in a very satisfactory manner. There is now no doubt at all about the value of serum in the treatment of this disease. This writer says that it is useless after the fifth day [but it is of little value after the third day]. There is also no doubt about the limitations of serum treatment. In type I pneumonia it will reduce the death rate from 14.7 to 9.8 per cent and in type II from 26.2 to 20.1 per cent; that is to say it will save the lives of 5 or 6 people in each hundred persons suffering from pneumonia—of either of these types—that were otherwise doomed to die. Though this is a definite result, it is not a dramatic one, and the advantages of this treatment might easily escape the notice of the doctor who has a limited experience in this disease; he should not therefore allow himself to be influenced too much by his own experience. On the other hand, to use expensive serum indiscriminately in all cases of pneumonia at any stage of the disease in this country where types I and II are less common than in England and America is obviously unjustifiable.

The second volume of articles on treatment is quite up to the standard of the first and to say this is to

accord it high praise. The price is a very reasonable one.

RECENT ADVANCES IN MEDICINE: CLINICAL LABORATORY THERAPEUTIC.—By G. E. Beaumont, M.A., D.M. (Oxon.), F.R.C.P., D.P.H. (Lond.), and E. C. Dodds, M.V.O., D.Sc., Ph.D., M.D., F.R.C.P. Eighth Edition. 1936. J. and A. Churchill Limited, London. Pp. xvii plus 450, with 46 illustrations. Price, 12s. 6d.

We have begun to look for a new edition of this the most popular book of that very popular series, 'Recent Advances', almost annually. This is in fact the eighth edition since 1924.

That there has been some revision in nearly every section is a tribute to the present generation of physicians and research workers; it is noticeable that most advances have been made with the aid of biochemical investigation. Some of the most striking have been made in our knowledge of hormones and ductless glands, and the section dealing with this subject is practically a new one. Vitamins are included in the same chapter and the information on these important accessory food substances has been brought up to date; this is mainly in our knowledge of their chemistry and there is little new about the clinical application of this knowledge. There is a table showing what is known about the six different substances constituting the vitamin-B complex; B3, B4, B5 and B6 are not yet as clearly defined as B1 and B2, and they appear to exhibit a tendency to change places with one another.

The section on anæmia has been extensively rearranged and new matter added. There is still no reference to the packed-cell method of estimating cell volume; it is difficult to see why this method fails to gain popularity in England. To the section on the stomach, the alcohol test meal method has been added but the ordinary, Rehfuß, method is still retained. The histamin method is also described. In the reviewer's experience the alcohol method is far easier and is distinctly more popular with patients. The results obtained are not exactly comparable to those with the gruel meal and for this reason it is a pity that some normal curves are not given.

A few omissions have been necessitated in order to prevent a serious increase in size of the volume, but these have been rather of the nature of compressions than actual omissions. The very excellent sections on kidney function and basal metabolism still remain, but with slight additions in the latter instance. The ketogenic diet is now increased to a ratio of 6 to 1 ketogenic to non-ketogenic substances; the reduction of the carbohydrates to 4 grammes a day seems rather a drastic procedure. There is no mention of mandelic acid in the treatment of *Bacillus coli* infections. Another omission is the use of histidine in the treatment of gastric and duodenal ulcer. But perhaps neither of these can yet be classed as established advances.

This edition deserves to be as popular as the previous ones.

L. E. N.

PROGNOSIS. VOLUME I. 1935. Published by the Lancet Limited (7, Adam Street, Adelphi), London. Pp. x plus 372. Obtainable from Messrs. Butterworth and Company (India) Limited (Sole agents in India and the East), Calcutta. Price, Rs. 7-12

It has been said of the trio, diagnosis, treatment and prognosis, that the most important is diagnosis, that the next most important is diagnosis, and that after this comes diagnosis. This may be true, but much is written about diagnosis, even more is written about treatment, and very little about prognosis. One of the reasons for this is that there is very little accurate information on the subject. No definite system of following up cases was practised even in the big hospitals in London until a few years ago, and

in many other hospitals this important source of information is still entirely neglected. The follow-up system is as essential a corrective to the physician who has such supreme faith in his treatment that he counts all patients as cured if they do not return to him for further treatment, as the post-mortem room is to the physician who has the same faith in his powers of diagnosis.

Prognosis is not simply a matter of statistics, though they form a very excellent basis. The patient does not want to be told that 50 per cent of sufferers from his disease recover completely, 30 per cent partially, and 20 per cent die; he will probably be egotistical enough to wish to know into which group he himself is likely to fall. There are many factors to be taken into consideration and it is only by experience that each can be given its correct value. Personal experience may be limited, and therefore the carefully weighed opinion of one who has had special experience will be of great assistance in this difficult matter of prognosis.

The articles that appear in this book have been published in the *Lancet* at various times. The reviewer has read them with interest from time to time, but in book form they make a much stronger appeal. They are essentially the type of article that one wants to refer to when the occasion arises, rather than to commit to memory, though of course a useful impression is left after reading them through once.

It is not necessary to discuss the individual contributions; they are all by authorities on the subject on which they write. It is interesting to read that the subjects were chosen by the contributors themselves, and were not suggested by the Editor; this is an important point, as they will obviously have chosen those subjects on which they feel most competent to express an opinion, and will not be simply written to order, as sometimes happens.

The short opening chapter on general principles by Robert Hutchison is particularly good and will bear reading more than once; every word has been well considered.

Congratulations are due to the publishers on the format of the book; the title page makes a particular appeal to the reviewer. It is a book that we can recommend to the practitioner for an important place on his reference shelf.

L. E. N.

RECENT ADVANCES IN LARYNGOLOGY AND OTOTOLOGY.—By R. Scott Stevenson, M.D., Ch.B., F.R.C.S. (Edin.). 1935. J. and A. Churchill Limited, London. Pp. x plus 346, with 128 illustrations including 13 plates. Price, 15s.

MR. STEVENSON has succeeded in producing a very useful book especially for post-graduates and for specialists both senior and junior.

The general practitioner will also find in it very useful and practical information, for instance in the chapter on conservative treatment of middle-ear suppuration.

The opening chapter deals with the tonsil problem. This time-worn subject he deals with fairly and without personal bias. He then deals with malignant disease of the pharynx.

He describes Coutard's deep x-ray technique and Berven and Cade's radium technique. The chapter on agranulocytic angina is interesting and up to date. The chapter on the mechanism of the larynx and voice is derived chiefly from the masterly work of Negus. Then he deals with cancer of the larynx, illustrating it with photographs of Broders' grading of cancers and of operations on the larynx.

There is a very useful analysis of the work of St. Clair Thomson and Colledge, and Harmer's radium treatment and deep therapy. Bronchoscopy and œsophagoscopy are reviewed in their relation to general medicine. Intranasal and external operations on the nasal sinuses are described fully and the order of operation indicated.

The section on otology is very full and includes a consideration of the Wever and Bray phenomenon with a comparison of the hearing tests with tuning fork and audio-meter.

The chapters on recent work on otosclerosis and Meniere's disease are very interesting. Neumann's method of dealing with meningitis of otitic origin gives the best chance of recovery.

The author is to be congratulated on producing an excellent review of the whole subject in the short space of some 350 pages. There is a very complete list of references at the end of each chapter.

The publishers are also to be congratulated for the book is well produced and

H. S. C.

AN EPITOME OF THE LABORATORY DIAGNOSIS AND TREATMENT OF TROPICAL DISEASES.—

By Horace M. Shelley, F.R.F.P.S., M.R.C.S., L.R.C.P., D.T.M. & H. (Eng.). 1936. (Pocket Monographs on Practical Medicine). John Bale, Sons and Danielsson, Limited, London. Pp. xii plus 81. Illustrated. Price, 2s. 6d.

It is claimed in the preface that this book is written to provide the 'busy practitioner' with concise information on the laboratory diagnosis and treatment of tropical diseases. For the purpose of providing the 'busy practitioner' in Africa with all he need know about tropical diseases that occur mainly in India, and conversely of providing the 'busy practitioner' in this country with necessary information on African diseases, the book should prove adequate; but we do not feel that the 'busy practitioner' in either country would remain busy if he had to rely entirely on the information given in this book for the treatment of his patients suffering from the local diseases. On the other hand, it is probable that it would provide the busy examiner with sufficient information to satisfy a busy examiner—in most temperate climates.

Under the diagnosis of relapsing fever we read—'The treponema itself is a coarse type of spirochæte, having seven to fourteen curves, and extending to a maximum length of 20 microns. It is very slender and has such a characteristic appearance that it cannot be easily mistaken'. This last sentence may be the truth, but we do not feel that the author has conveyed to us an entirely unmistakable impression of what this coarse slender spirochæte looks like. Nor are we assisted by the crude line drawing.

The technique for 'blood counts' is very inadequate and one wonders whether it was worth including at all. The Tallqvist method for estimation of hæmoglobin is the only one mentioned, and the normal standards are obviously copied from English textbooks.

Under infective jaundice it is stated that the 'organism is found in the blood and urine in the first three or four days of the disease'. There is no mention of berberine sulphate in the treatment of oriental sore, nor of Frei's test in the diagnosis of climatic bubo. The dosage of neostibosan given on page 20 does not coincide with that given on page 75. A dose of 0.02 grammes of plasmoquine four times a day is advocated.

The author considers it 'rather farcical to rid a native patient of his hookworms by carefully controlled hospital treatment knowing that he will be reinfested', and considers that 'he should be instructed how to avoid becoming reinfested'. We agree with this last remark, but we think that the author might have let us into the secret too. Tetrachlorethylene is not mentioned, and, though the dangers of carbon tetrachloride are emphasized, there is no mention of the special danger in alcoholics.

Nevertheless, there is much accurate information in the book, quite sufficient, as we have said, to satisfy many examiners.

L. E. N.

GREAT DOCTORS OF THE NINETEENTH CENTURY.—By Sir William Hale-White, K.B.E., M.D., LL.D. (Hon.), F.R.C.P. 1935. Edward Arnold and Company, London. Pp. vii plus 325. Price, 15s.

ENGLISH literature is by no means rich in medical biographies and any worthy additions to the historical shelves of our libraries are very welcome indeed. These seventeen essays on distinguished doctors of the last century are important from an historical point of view, and they also form very good reading matter.

The biographies are peculiarly satisfying, but it is hard to say what is the particular quality that makes them so. We are told a little about the forebears of each of these great men; although in some cases this amounts to little more than the classical opening of the 'poor but honest parents' type, it is sufficient to create a picture of their home surroundings and to allow one to trace the effect on the later lives of the subjects. Then an account is given of their early struggles, more often for a livelihood than for recognition. There is little suggestion that any of these men felt that they were personally endowed with the divine spark; most of them had their enemies and their quarrels, but, with one outstanding exception, they do not seem to have suffered delusions of persecution. Some might think that the book contains too many references to salary and earnings; but the correlation between these and opportunity and experience is such a close one that they are crucial factors in the lives of most medical men; great medical discoveries cannot be made in a garret.

Contrasts between the different lives is interesting. When Simpson died every shop in Edinburgh closed for the day and the Queen sent messages of condolence. Addison's death was not even marked by an obituary notice in the *Lancet* or *British Medical Journal*. Yet to-day Addison's name is the more familiar.

The first chapter is on Jenner, the last on Ross. The author shows Ross as a dilettante littérateur and minor poet who made a short but brilliant essay into medical research and then retired (not from salaried appointments, but from active medical research) and wrote about it for the rest of his life. In 1895 Ross was writing books and poetry when he got the idea from Manson that mosquitoes might transmit malaria. He returned to India, proved the theory, and left India again within four years. 'After he left his official post in India he did no original work, saying he had lost heart for it, because of early opposition, and because of the attempts to deprive him of priority'. This is perhaps hardly doing justice to Ross.

Sir William is not a writer of beautiful and smooth English. He tends to use too many short staccato sentences—but for the medical reader and especially for the reader in India this is an error on the right side—and he is careless with his pronouns. The early misgivings that the reviewer entertained—on reading the opening sentence of the preface—were mercifully not fulfilled. Sir William has made an important addition to literature of medical history and we can thoroughly recommend the book to both medical and other readers.

L. E. N.

FOR AND AGAINST DOCTORS: AN ANTHOLOGY.—Compiled by R. Hutchison and G. M. Wauchop. 1935. Edward Arnold and Company, London. Pp. 168. Price, 7s. 6d.

It is particularly annoying to read a book almost to the end, to pause and decide what you will say in your review, and then to find that this has already been said in the last two pages of the book in a 'retrospect'. Here is quoted the remark of an American writer that 'all the real, solid, elemental jokes against doctors were uttered some one or two thousand years ago'. The remark is also true of the criticism and abuse of doctors. Perhaps the most striking thing about this earlier criticism was its vulgarity—viewed from a

present-day standpoint—and the singular absence of wit. 'Who has a physician has an executioner' and 'The best of doctors is ripe for hell' strike one as being abuse without any subtlety.

The Emperor Hadrian directed that the words 'A multitude of physicians have destroyed me' should be inscribed on his tomb; to this we should like to have added *Punch's* remark, 'One physician is better than two, but three are fatal'. Both might well be remembered in this country where it is fashionable to call in a series of half a dozen consultants, to get prescriptions from each, and then to use none of them—perhaps better for the patient than giving them all. There is another remark, which, though made in the 13th Century in England is applicable to-day in India—'Medical men are ignorant of simple medicine, and at the mercy of uneducated apothecaries'.

Very much more welcome is reasoned criticism of the profession. Francis Bacon supplied plenty of this. 'For in all times, in the opinion of the multitude, witches and old women and impostors have had a competition with physicians. And what followeth? Even this, that physicians say to themselves, as Solomon expresseth it on a higher occasion, 'If it befalleth me as it befalleth to the fools, why should I labour to be more wise?' Ninety per cent of the defects in the profession can be traced to this attitude of mind, which should be guarded against at all costs, but it is the quacks within the profession that set the bad example to the young practitioner to-day.

We are able to stand up against the unjust criticism of our enemies, but save us from our friends! Ruskin wrote 'if they are brave and well educated, the entire object of their lives is not fees. They, on the whole, desire to cure the sick; and—if they are good doctors, and the choice were fairly put to them—would rather cure their patient, and lose their fee, than kill him, and get it'. Or, in other words that most—but not all, mark you—doctors would hesitate to murder their grandmothers for the gold in their false teeth. High praise indeed!

On the other hand, most of us will feel a little self-conscious on reading Stephen Paget's opinion of our profession—'If a doctor's life may not be a divine vocation, then no life is a vocation, and nothing is divine'. It is, however, an ideal up to which we might all attempt to live.

We can recommend this book to all doctors, and to their patients and friends as a suitable and inexpensive present to give to a doctor.

L. E. N.

OBSTETRICAL PRACTICE.—By A. C. Beck, M.D. 1935. Baillière, Tindall and Cox, London. Pp. x plus 702, with 1,043 figures. Price, 32s. 6d.

THE first impression experienced by many medical men on seeing a well-got-up and profusely illustrated new textbook is one of suspicion; there have been too many such whose excellence lay in their get-up rather than in their material. It took a very short examination of Beck's *Obstetrical Practice* to dispel this suspicion, and longer study changed it into admiration. It is a new textbook which should set up a standard for others, especially in those sections dealing with the various mechanisms of labour.

The author, who is professor of obstetrics and gynaecology in the Long Island College of Medicine, has a wide experience in teaching post-graduate students, and he believes that most of their difficulties in obstetric deliveries have been due to their lack of knowledge of the mechanism of labour. Accordingly he devotes more than a third of this large book, and more than 600 illustrations, to this subject. After a good description of the powers, the passages, and the passenger, each accepted mechanism and its management is described separately, and illustrated by four series of drawings. Each series shows the course of labour as seen from one standpoint. It is chiefly through these illustrations, and only to a minor extent

through the text, that the author seeks to teach this subject; their number may sound excessive, but there are none which do not illustrate a point well, or with which the reviewer would dispense. It would be a poor student who could study these chapters seriously and still remain deficient in his knowledge of the mechanism of labour.

Another subject to which the author devotes more than usual attention is the medical and surgical complications of pregnancy. They are dealt with in eight sections, to each of which is attached a bibliography of some twenty to thirty references, and many complications not normally referred to in a textbook are described. In this chapter, and this chapter alone, there appears to be a lack of balance. The average student would prefer that some of the common complications were more fully dealt with, even if it meant the exclusion of reference to some of the more rare ones. The practitioner in India is used to seeing his bug-bear, anaemia, ignored, so it is a pleasure to see it recognized here, even though it is only to be briefly and not too accurately dismissed. But surely the aetiology, pathology, symptomatology and treatment of pyelitis deserve more than a single page!

The physiology and pathology of the foetus, pregnancy, and the puerperium receive as good treatment as does the mechanism of labour, though the author relies more on the written word than on illustrations. His writing is avowedly for the learner and not for the expert, so that a rather dogmatic presentation of his own opinion is given, to the exclusion of conflicting theories. This makes for clarity and simplicity, whilst its tendency to produce a narrow-minded outlook in the student is fully offset by the short bibliography at the end of each chapter, which is designed to help him to go more deeply into the subject.

The book bears, throughout, the imprint of a single author, which gives it a great advantage in continuity of thought and method over most complications by bands of experts. The reviewer read it with interest and advantage from cover to cover, and found so few minor points to criticize that to mention any of them would seem to overweight the review with criticism. It should at once be recognized as being in the front rank of textbooks of obstetric practice for post-graduate as well as under-graduate students.

G. M.

COMMON SKIN DISEASES.—By A. C. Roxburgh, M.A., M.D., B.Ch. (Cantab.), F.R.C.P. (Lond.). Third Edition. (General Practice Series.) 1936. H. K. Lewis and Company Limited, London. Pp. xxxi plus 377, with 8 plates in colour and 139 text illustrations. Price, 15s.

THIS book was first published in October 1932, and that it was deservedly appreciated was shown by the fact that a second edition was needed by July 1934, this edition was even more quickly exhausted, for the present volume, the third edition, appeared in January last.

The book is practically the same size as the former editions but a few paragraphs have been added and a little touching-up elsewhere has been done. The illustrations have also been improved by the replacement of eight of the original ones and the addition of eleven others. The author has also found it necessary to give his prescriptions in both the metric and British measures thus showing the book is appreciated outside the English-speaking world.

In our review of the second edition we expressed the hope that the author might gradually increase the size of his book as it appeared an excellent foundation on which to construct a large textbook. He has not done so and on second thoughts we are inclined to agree with him for in this book he has supplied all a general practitioner needs for his occasional dermatological cases, and if the size of the book is increased it will lose one of its most valuable characters. Increase in size would also mean increase in price and

this would remove another of the outstanding characters of the book for we are not acquainted with books in any other branch of medicine which give such good value for the sum of 15 shillings, and in this connection the publishers merit praise as well because this book lacks nothing in quality of production on account of cheapness.

P. A. M.

A SYNOPSIS OF PHYSIOLOGY.—By A. Rendle Short, B.Sc., M.D., F.R.C.S., and C. I. Ham, M.B., B.Ch., F.R.C.S. (Ed.). Second Edition. Edited by C. L. G. Pratt, M.Sc., M.D. 1936. John Wright and Sons, Limited, Bristol. Pp. 312. Illustrated with coloured and other diagrams. Price, 10s. 6d.

THIS is a very handy little book containing up-to-date information on modern physiology within a short compass. The subject-matter has been nicely dealt with and is well arranged. The chapter on chemistry and the tests for detection of the substances of physiological importance have increased its usefulness. The students going up for their university examination will find this book very suitable for general and quick revision of the subject of physiology.

P. D.

THE EXTRA PHARMACOPŒIA OF MARTINDALE AND WESTCOTT. Twentieth Edition. Volume II. 1935. Published by Direction of the Council of the Pharmaceutical Society of Great Britain, The Pharmaceutical Press, London. (23, Bloomsbury Square, W.C. 1). Pp. xxxvi plus 889. Price, 22s. 6d.

IN the twentieth edition of this book, the general arrangement of the subject-matter of the previous editions remains practically unaltered, but in view of the

recent complete revision of the *British Pharmacopœia* and the *British Pharmaceutical Codex*, numerous chapters bearing on scientific progress associated with medicine, chemistry and pharmacy have been added. Scientific papers and abstracts published in various journals have been fully made use of in revising this treatise.

This volume deals chiefly with the analytical, experimental and research work and many other subjects associated with different branches of medicine. The present edition has been to a great extent rewritten. This change was rendered necessary by the increase of knowledge obtained during the last few years. The subject-matter is well reviewed to the minutest detail and the chaff carefully winnowed from the grain.

The section dealing with hormones and glandular products has been very much expanded. The study of the endocrinologic problem from a standpoint of physiology and pathology, as well as therapy, has been very widespread and the growth of this form of therapy has been steady and progressive in all parts of the world. Recent advances with special regard to therapeutics are incorporated in this volume and an account of the methods of standardizing different hormones will be found outlined with transparent clearness. The chapter dealing with hæmatology has been submitted to a detailed examination and the accepted views and methods considered of value to medical practitioners has been well summarized. Some of the older methods of blood analysis have been replaced by less cumbersome modern micro-methods.

In a work that is worthy of so much praise and deserving of so little criticism the function of a reviewer is difficult. The work is remarkable for the manner in which the newest results of research are brought together. We have no doubt that this edition will maintain the prestige which its predecessors have won.

Abstracts from Reports

REPORT ON THE HEALTH OF THE ARMY IN INDIA FOR THE YEAR 1934. VOLUME LXX

NOTES ON DISEASES

Cerebro-spinal meningitis.—Cerebro-spinal meningitis has in recent years been increasing to a marked extent among the civilian population of India. This increase is reflected in the incidence among Indian troops, but among British troops only two cases (one fatal) have occurred.

The incidence has fallen largely on recruits, 18 of the 38 cases among Indian troops falling into this category.

The mortality rate of 1934 was considerably lower than that of previous years. While, no doubt, there are many factors involved in this result, it is not without interest that it coincides with the adoption of a three-times concentrated therapeutic serum (which is the only type now used), and with the more general adoption of the policy of administering this serum intrathecally in daily doses from the earliest possible moment until the issue of the case is beyond doubt. In those cases which recovered (excluding one case—a boy—where treatment was refused by the parents), the average quantity of serum given in each case was 119 c.cm. intrathecally, and 86 c.cm. by other routes.

In one hospital, in addition to this routine treatment, iodine was administered intravenously. Of eight cases so treated only two died. Three of the eight cases were classed as very severe, three as severe, and two as moderately severe, so that the results may be regarded as good. This method of treatment merits, and is receiving, further investigation.

Cysticercosis.—Two cases of this disease were diagnosed in India, one of which was rapidly fatal. Much

attention has been directed to the hygienic control of piggeries and to the examination of pork, in the hope that a decrease in infestation with *T. solium* (40 cases of which occurred among British troops) may lead to a corresponding decrease in cysticercosis. All officers are alive to the importance of this subject, and all known steps for the prevention of the disease are being taken.

Dengue.—The incidence during 1934 is the lowest that has been recorded in the last ten years. As in previous years, the disease is confined mainly to the garrisons of ports.

The incidence of dengue bears a close relationship to that of malaria, in most years the incidence of malaria is approximately ten to twelve times that of dengue.

Sandfly fever.—Research on this subject has suffered an unfortunate check through inability to maintain continuity in the appointment of officers specially selected for the investigation of this disease.

Under the conditions which at present exist in the localities where this fever is most prevalent, it is not practicable to prevent sandflies from breeding. Nor are the climatic conditions in these localities such that the use of small-mesh nets can be advocated. As funds permit, old and unsuitable barracks in certain of these stations are being replaced by buildings of improved construction and design, from which it will be much easier to eliminate sandflies. It is hoped that this measure will give rise to some improvement.

Fevers of the typhus group.—The increased number of cases of fever of the typhus group, which has been reported this year, does not necessarily indicate an increase in the incidence of the disease. It is more probably a sign of the greater interest which is being

taken in this condition and of the improved methods of diagnosis which are available.

Special case sheets have been maintained for all these cases, and an examination of the results of 110 cases among British and Indian troops of all ranks, and their families, reveals various points of interest and importance which have not previously been fully realized.

The Indian form of this disease is commonly known as Indian tick typhus, although this designation has not been used in army nomenclature since 1932. The generally accepted idea was that only one type of the disease existed in the country.

As the result of testing the serum of all cases against standardized suspensions of the 'O' antigen of *B. proteus* X2, XK, and X19, it has been definitely shown that a type of typhus, closely related in its clinical and serological characters to 'scrub typhus' of Malaya, is to be found scattered throughout India. In the period under review this type had a very definite seasonal incidence, the vast majority of cases occurring between the middle of August and the beginning of October—i.e., during the latter portion of the monsoon. The rash in these cases was relatively inconspicuous and disappeared completely in about seven days. There was a well marked rise in agglutinins of the XK type, accompanied by practically no co-agglutinins for X2 and X19. No evidence was forthcoming as to the vector; none of the cases gave any history of tick bite. By analogy, it seems possible that a mite may be responsible.

Another type of the disease, first appearing in July and rising to maximum in December, occurred chiefly in certain districts in the Southern Command. This is undoubtedly the form which has been described as 'Indian tick typhus'. The rash in this type of the disease differs in certain important particulars from that which occurs in XK type. It is much more conspicuous, is generalized in distribution—being present on the palms and soles—and is of prolonged duration, persisting in certain cases for a month or more, the average being from two to three weeks. On the whole, the symptoms are more severe in this than in the XK type. The serological results in these cases are variable; in some, agglutinins for X2 predominate; in others, the balance is in favour of X19. It would appear that this is probably a group response, and that the strain of *B. proteus*, which embodies the main antigen of this virus, has yet to be discovered. In the 1934 series of cases there is no evidence that the patients were bitten by ticks, and the question of the vector must remain an open one, although there are undoubtedly grounds for suspecting the tick. This matter is being investigated. These cases bear a very close resemblance to the Rocky Mountain fever, *Fièvre Boutonneuse*, and African tick-bite fever, differing from the latter two in not showing a primary lesion.

A third type of the disease is found chiefly in the South of India, the majority of cases having occurred this year in Bangalore. Most of the patients were Indians and showed no rash. A transient rash of varied type and distribution appeared in 5 of the 6 British cases. This type had no definite seasonal incidence, but was absent during the hot weather months. The serum in most of the cases agglutinated X19 to a high titre. It is, of course, possible that this type may be merely a variant of the second type, but on the whole there is good reason to regard it as a separate entity, possibly a member of the endemic typhus (flea-borne) sub-group. There is no evidence of either tick or louse transmission. Experiments with rats and rat fleas have, up to date, been negative.

Certain cases have occurred which, in the absence of further information, cannot at present be placed in any of these three groups. Three cases had a fatal termination. It is considered that all of these belonged to the second group.

An interesting point common to cases of all types, and one which explains why the correct diagnosis has

been overlooked in the past, is that many of them show a well-marked rise in agglutinins for one or other of the enteric group organisms. Blood cultures have, of course, been carried out and have given negative results in this respect.

It is proposed to make use of absorption tests to throw further light on the exact nature of these agglutinin reactions against both proteus and enteric strains. A few cases have developed a positive Wassermann reaction which generally subsided to negative during convalescence. These fevers have been almost entirely confined to males. In the series of 110 cases, one, which occurred in a girl aged 10, is the only exception.

Pyrexia of uncertain origin.—The number of cases classified under this diagnosis continues to decrease.

Diphtheria.—Sporadic cases continue to occur, and the figures have remained at a very constant level. There has been no outbreak of an epidemic nature among British troops.

Enteric fevers.—The incidence among British troops has decreased almost by half, reaching a lower level than has ever previously been touched. Among Indian troops the decrease which has been in progress in recent years has been maintained, but this is in no way proportionate to the very marked drop which has occurred among British troops. Deaths have been halved among British troops, and decreased from 23 to 15 among Indian troops.

There has been no epidemic outbreak among the troops, the majority of cases having been sporadic in nature. Occasional groups of two or three cases have occurred denoting a common but transient source of origin. In the examinations of menials which were carried out during the year (10,572 men being examined with a total of 35,895 tests), 7 carriers (six of *B. typhosum*, and one of *B. paratyphosum*) were discovered. The absence of outbreaks bears witness to the fact that the system which is in vogue is producing the desired result.

Dysentery, diarrhoea, colitis and amœbic hepatitis.—The admission ratio is the same as that for 1933. The average constantly sick ratio, the average sick time in days, and the average number of days lost per 1,000 of the strength per annum, all show slight decreases, indicating that the type of case was less severe than in the previous year. Ten men were invalided (5 for amœbic dysentery, 5 for bacillary dysentery) as opposed to 8 in 1933, but there were no deaths (one in 1933).

In practically every other disease except dysentery, the general improvement in the hygienic environment of the soldier has led to a decrease in incidence. In dysentery the general trend is in an upward direction in spite of all the measures that have been taken to control it. The widespread distribution of the disease in the civil population and the primitive system of disposal of excreta which exists in most stations, combined with the presence of flies, create a problem which has so far defied solution.

The general lines of treatment remain the same, and are, on the whole, satisfactory. The great majority of cases were of a mild nature.

The incidence of dysentery in Quetta remained at a high level during the first eight months of 1934. Thereafter the figures were below those of 1933, and it seemed possible that the outbreak was abating. Subsequent figures support the view.

The scheme of classification of dysentery bacilli which was introduced three years ago continues to give satisfactory results, and it is possible to recognize immediately all but a small proportion of the dysentery bacilli which are isolated.

Investigations of the mannite-fermenting organisms which are still unclassified continue. One other type which was identified during the original investigation, but which was at that time very rare, has since been found to occur not uncommonly in other parts of India. Its antibody has therefore been included in one of the

diagnostic polyvalent sera which are issued. Accumulating evidence, which it is hoped to publish in the near future, seems to confirm that all these new types are actual causes of dysentery.

Malaria.—The 1934 figure is better than the previous best by no less than 16.6 per 1,000.

These are remarkable figures, but it would be a big mistake to imagine that they are likely to be surpassed, or even maintained. The recent severe epidemic in south-west Ceylon, and the history of malaria in India itself, are a warning against premature optimism. Before exchanging caution for confidence, it is essential to consider, in a comparative way, all the important aetiological factors that may influence the incidence of this disease. It is thought that examination of the statistics, coupled with comparative study of the aetiological factors, will tend to the opinion that, of late, a real and permanent improvement has occurred in the malaria situation in the army in India.

Now and again disturbing influences may, and almost certainly will, arise to lower the present record incidence. For example, were financial stringency to become more intense, no doubt the anti-malaria grant would be still further reduced; were operations in the field to be undertaken during adverse weather conditions, the unpleasant experiences of 1933 would inevitably be repeated; or if for some reason such as war, the supply of plasmoquine were interfered with or stopped, then the proportion and severity of the relapses would revert to the standards which existed before 1932. Such checks to progress are beyond medical control.

It is now proposed to set forth the grounds on which is based the belief that a real and permanent improvement has occurred; and for this purpose the past three years, 1932 to 1934, will be compared.

The periodicity of epidemic malaria is an important factor. In one of these years—1933—this factor was encountered in a severe form in the north-western sector of the country, where so many of the troops are stationed. There, a number of the garrisons suffered heavily, and yet the admission ratio per 1,000 was only 103.3, at that time, the third in order of merit since 1921. Apart from periodicity, meteorological conditions are those which exercise the dominant influence in the incidence of this disease in India.

In 1934, and speaking generally, meteorological conditions were adverse. They presaged a comparatively heavy malaria toll.

To summarize:—The active period (June to September) of the monsoon of 1934, over the whole of India, yielded a rainfall which varied from normal to excess. In some areas the excess was great, and affected a number of important military localities. In the transition period (October) rainfall was more or less in defect. Over some areas, including those in which the bulk of the troops are stationed, the defect was marked. The meteorological review leads to the opinion that in 1934 weather conditions were against a good malaria year.

In comparing annual incidences of malaria with annual meteorological conditions, there are, of course, a number of concomitant factors, the presence or absence of which must be taken into account. The periodicity of epidemic malaria has already been mentioned. Also, it must never be forgotten that, whereas in a particular year general meteorological conditions may be adverse, locally they may be quite favourable; extensive areas may be heavily rained upon and flooded, while cantonments in the same district may have the luck to escape. Then there is the factor of 'carry-over' of cases. Unfortunately, the statistical year does not coincide with the true malaria year. Any statistical year under review may have been preceded by a good or a bad malaria year and its figures will be favourably or adversely affected accordingly. Finally, there must be taken into account the fortuitous factor, field service; and also its allied condition, civil disturbance. The circumstances of war

and of active internal policing are, by their nature, powerfully antagonistic to malaria prophylaxis.

In 1934 epidemic malaria did not occur. Local meteorological conditions were generally adverse, and often markedly so. The 'carry-over' from 1933 was fairly heavy. The position was not handicapped by war or by civil disturbance.

Details regarding the corresponding factors in 1933 and 1932 may be studied in the reports on the health of the Army (India section) for the appropriate years. They are shown below in tabular form. A plus sign indicates that the factor was favourable to a good malaria year; a minus sign indicates that the factor was adverse.

	Epidemic malaria	Weather conditions	'Carry-over'	War and civil disturbance
1932 ..	+	—	—	—
1933 ..	—	— — —	+	—
1934 ..	+	— —	—	+

In itself, this rough picture is of no value; but if its constituents are examined separately and compared, it will be seen, firstly, that expectation would have made 1933 a worse year than it actually turned out to be; and secondly, that expectation would not have made 1934 as good as it turned out to be. There were grounds for forecasting that 1934 would be an improvement on 1933; but, on the above factors alone, there were no reasons for supposing that the 1934 figures would surpass those of 1932.

In the interests of prophylaxis, it is necessary to formulate an opinion as to why the 1934 statistics are so eminently satisfactory. The term 'eminently satisfactory' is used purposely instead of 'surprisingly satisfactory', because it is believed that certain comments and prognostications made in these reports during the past three years have now been justified. These concern three additional factors, *viz*, the effect of the new synthetic drugs, plasmoquine and ateb'in; the improved standard of anti-malaria field work resulting from the training at Karnal; the re-awakening of interest, and the application of more scientific methods, among the clinicians.

As these matters have already been dealt with in recent reports, it is only necessary to revert to them briefly now. It is beyond doubt that quinine-plasmoquine, as used in military medical practice in India, results in a more radical and more rapid cure of malaria than does the administration of quinine alone. It is also beyond question that ateb'in-plasmoquine effects a quicker cure than does quinine alone.

In certain cases quinine will continue to be more or less commonly employed; it has its advantages. In others ateb'in and/or plasmoquine are the drugs of choice—though it is not contended that these drugs, used singly or in combination, are complete and perfect remedies. They merely signalize a great step forward in malaria therapeutics. How great that step is may be measured with a fair degree of accuracy by comparing the total admission rates, on an all-India basis, from year to year; by studying the ratios of relapse to fresh cases; and by noting the varied lengths of time considered necessary to rid a patient's system of parasites, in accordance with the particular form of treatment prescribed.

Mention has already been made of the remarkable fall in the all-India admission ratio; and it has been pointed out that this decline is not confined to the year under review. Even in a very bad year (1933) the ratio was much below expectation.

As regards the relapse rate, the following is an extract from remarks in an annual report for 1934, made by a competent and reliable observer:—

'It seems clear that fresh cases of malaria are very rarely, if ever, contracted in the military cantonments of the Madras district. *A. subpictus* and *A. fuliginosus* have been identified in Madras and Bangalore, but none of the anophelines usually recognized as carriers.

Analysis of all the cases in the Q. V. O. Madras Sappers and Miners, Bangalore, the largest source of our malaria figures, shows that every case except one was admitted to hospital within a week of returning to Bangalore either from leave to his home, camp duty, or duty in frontier stations.

The treatment of these cases by plasmoquine and quinine or plasmoquine and atabrin, as per D. M. S. Circulars, has been so successful that *there has been no relapse for two years in a total of 112 cases*. The absence of any possibility of local re-infection makes Bangalore very suitable for judging the results of treatment'.

If we pass from this to an area where re-infection within cantonment limits is an everyday occurrence, we find the Assistant Director of Hygiene and Pathology, Northern Command, remarking thus:—

'The command relapse rate has fallen to 36.7. Many of the relapse cases were, however, the result of fresh infections contracted in 1933, during the Mohmand-Bajaur Operations'.

This is very different from the state of affairs which prevailed before the advent of the new drugs, when the relapse rate was customarily round about 90.

In the report for 1933, it was shown that relapse rates vary according to therapeutic and nursing conditions; and that these conditions were classified under 'specialized', 'selected' and 'general practice'. Other things being equal, it may now be said, with confidence, that the following are conservative estimates of the relapse rates in these three classes:—

Specialized 8 per cent or under.
Selected Average, 12 per cent.
General practice Maximum, 30 per cent.

If these figures are exceeded, there is something amiss with the treatment of the patients; an extraneous factor is at work, such as war, or the effects of war, or re-infection is taking place. In making a differential diagnosis, fresh or relapse, this question of re-infection is an extremely difficult one to settle; and especially so in that area—the Punjab and the frontier—from which so much of the Army malaria comes. (The conditions in Bangalore are very exceptional). However, it is not for this reason that the table showing fresh and relapse cases, by commands, has been omitted from this year's report; the omission is due to the following circumstances:—

In order to make the cases against the new synthetic drugs as black as possible—in order to eliminate personal prejudice in their favour—it was decided that *all* admissions subsequent to a primary admission should be regarded as relapses; that the question of re-infection should not be considered at all.

The results were disappointing. Quite early in the malaria season it became plain that many cases labelled relapses were, in fact, re-infections.

The issue was further complicated by the fact that, in the Waziristan district, and throughout the Southern Command, an experiment on a big scale was in progress with the object of shortening the quinine-plasmoquine course of treatment. In the above areas, this course was cut down from the routine period of 21 days to 14 days. This must have resulted in the inclusion of a still bigger percentage of re-infections under the heading of relapse—particularly in the case of Waziristan where (as in the rest of the Northern Command) the risk of re-infection during the malaria season is abnormally high; very much higher than in the Southern Command.

Despite the unfair weightage above described, the relapse (so-called) percentages were well below

expectation, and much below those met with in the days before the new drugs were brought into use. In the Southern Command the percentage was 25; in the Waziristan district, 40; and over all India, 36.

In the forthcoming malaria year, it is not proposed to continue the short 14-day course of quinine-plasmoquine in the Waziristan district and the Southern Command; and it is not intended to fetter the diagnostic discretion of medical officers in the matter of relapse *versus* re-infection. It is confidently anticipated that these changes will result in a marked improvement in the fallacious relapse percentages of the year under review.

Improvement in the standard of field work continues, as more and more Karnal-trained officers become available. Nevertheless, supply does not equal demand, for qualified officers of the Royal Army Medical Corps return to England from time to time, tour-expired; and those of the Indian Medical Service are not infrequently transferred to the civil side, their services thereby being lost to the Army. It would be of great benefit to the Army if more military medical officers could be trained annually at the Ross Field Experimental Station for Malaria, Karnal.

Finally, mention must be made of the clinicians to whom too little credit for the improved malaria statistics has been awarded in recent years. The medical specialists in particular have devoted much time and attention to the therapeutics of the disease; and their investigations and reports thereon indicate a big advance in scientific outlook and practice.

Of other aspects of the anti-malaria problem there is little fresh to be said. As mentioned in these reports for 1932 and 1933, finance was subject to a severe 'cut' in 1932. This 'cut' still remains in force. So, too, does the decision arrived at in September 1931, that: 'In view of the present financial stringency, no further new works in the direction of mosquito-proofing of buildings should be undertaken until the financial situation is more normal'.

In connection with mosquito-proofing a curious and instructive incident occurred at Allahabad. Owing to the fact that most of the malaria contracted in that station was traceable to garrison duty in the old fort, it was decided to proof the building. The work was completed in January 1930 at a cost of little over £1,350. The admission ratio per 1,000 for malaria at Allahabad, averaged over the years 1925 to 1931, was 109. In 1932 it was 49; and in 1933, 40. In May 1934 the whole fort was denuded of its mosquito-proofing. This measure was carried out at the instance of the local authorities, after sanction had been obtained from command headquarters. The reasons put forward in support of this retrograde step were, that the netting shut out light, interfered with ventilation and collected dust and debris to such an extent that cleaning became impossible. In 1934 the admission ratio rose to 120 per 1,000.

One of the most encouraging features of the year 1934 was the interest shown here and there by authorities other than military in the anti-malaria problem. With the exception of Quetta, this interest was neither intense nor financially adequate; but a beginning has been made, and it is hoped that, from this, the participation of civil and municipal authorities in the anti-malaria fight will develop.

Although malaria remains the scourge of the British Army in India, the portents—as measured by sustained, if gradual, progress—are encouraging.

Tuberculosis.—There were 56 admissions for pulmonary tuberculosis, with one death and 51 men were sent home as invalids. The ratios per 1,000 were: admissions 1.0, deaths 0.02 and invalids sent home 0.94. Tuberculosis of other organs caused 8 admissions, one death, and 10 men to be sent home as invalids.

Diseases of the respiratory system.—There were 1,185 admissions, giving a ratio of 21.8 per 1,000. In 1933 the ratio was 21.8.

Acute and chronic bronchitis and catarrhal pneumonia accounted for 81 admissions, with 3 deaths and

6 invalided home. There were 90 cases of pleurisy, and 46 of laryngitis. Lobar pneumonia caused 176 admissions (3.2 per 1,000) as compared with 142 (2.6 per 1,000) in 1933. There were 9 deaths and the case mortality was 5.1 per cent against 7.7 per cent in 1933 and 12.8 per cent in 1932.

ADMINISTRATION REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES FOR 1934. CEYLON GOVERNMENT

During the year 1934 Ceylon has been fortunate in respect of the major communicable diseases, as there were only 35 cases of plague and the average for the previous five years was 62. There was one case of cholera which is the first recorded on the island since 1931 when there were six cases. Smallpox also seems to have been brought under control because in 1933 there were 337 cases and in 1934 there were only 72. Of the total deaths registered in the whole island from dysentery the percentage among Indian immigrants fell progressively from 1929 to 1933 from 32.5 per cent to 17.5 per cent but increased again to 21.5 per cent in 1934. The incidence of this disease also showed an increase from the previous year for there were 5,804 hospital cases and 34,369 outpatients treated for this disease in 1934 against 5,299 hospital cases and 22,614 outpatients in 1933.

Leprosy.—During the year 1,242 cases with 100 deaths, as against 1,227 cases with 76 deaths in 1933, were treated at the Government hospitals including the two asylums which are maintained in the island for the segregation of lepers.

The two leprosy survey officers started, in August 1933, the survey of Colombo city and during the earlier part of 1934 the survey was completed. Then the areas for survey were extended from the municipal to the rural areas of the Colombo district and at the end of the year the survey of the Colombo district and a portion of the Kalutara district was completed. During the latter half of October 1934, the survey officers visited the Batticaloa district and reviewed the work in that area.

The area surveyed during the year was 1,100 square miles in extent, having a population of nearly 1,250,000 inhabitants.

During the year 3 treatment clinics were opened in addition to the already established Central Clinic in Colombo.

In the areas surveyed in 1934, the officers detected 504 cases, of which 19 were in the Eastern Province, 112 in the city of Colombo, and 373 in the Western Province.

Yaws.—The following table shows the number of cases and deaths in the past five years:—

	1930	1931	1932	1933	1934
Hospital cases.	1,640	1,200	1,352	1,043	795
Hospital deaths.	5	4	4	3	2
Number of cases treated at dispensaries.	23,684	24,708	23,208	18,368	10,366
Total number of deaths for the island.	10	4	9	5	8

The continued decrease in the number of cases coming for treatment testifies to the success of the work of the *parangi* campaign. The itinerant medical officers who numbered 13 in 1930 were further reduced

from four to two in 1933. The work of these two officers had to be suspended from November 1934, owing to the malaria epidemic.

Malaria.—Malaria, the most prevalent disease in the island, assumed epidemic proportions towards the end of the year. The hospital admissions for the disease were 41,551 cases, as against 23,101 in the previous year, and the cases treated at the dispensaries and outpatients' departments of hospitals were 2,293,224, as against 1,199,075 in 1933. The epidemic started about the middle of October in Alawwa, Polgahawela, and surrounding villages and rapidly spread to other areas. It was most severe in the valleys of the three rivers—the Mahaoya, Deduru-oya, Kelani-ganga, and their tributaries—the provinces involved being the North-Western, Central, Sabaragamuwa, and Western. There were 988 deaths in hospitals from malaria in 1934, giving a death rate of 2.4 per cent as contrasted with 484 deaths with a rate of 2.1 per cent in the previous year. During the epidemic the proportion of cases of the malignant type of the disease was greater than normal and many deaths were due to cerebral malaria and to convulsions among children.

Ankylostomiasis campaign.—Marked progress in the campaign against ankylostomiasis was made in the year 1934, the number of treatments given during the year being the highest since the commencement of the campaign in 1916. That this result should have been achieved in spite of the almost complete suspension of activities during December on account of the widespread epidemic of malaria is extremely satisfactory. The benefit resulting from the campaign is well shown by the following quotation from the Registrar-General's report for 1933:—'The vigorous campaign conducted against the disease by the medical department has reduced the number of deaths and the death rate considerably in recent years, and the number of deaths fell from 1,955 in 1932 to 1,877, while the death rate which stood at 443 per million in 1930 and 363 in 1932 fell to 347 in the year under review, a rapid and striking decrease considering the small period in which it was effected'.

The average egg-count for the island which was 1,600 in 1933 was found to be 2,000 in 1934, and the percentage infected 81.2, as against 74.1 in 1933. A 50 per cent reduction in egg-count was effected as a result of treatment.

Poisoning after hookworm treatment.—Eleven cases of patients showing symptoms of poisoning after treatment were reported during the year, with nine deaths, giving the very low incident rate of less than 6 per million treatments.

A special conference was held to consider the question of poisoning. Dr. P. A. Maplestone of the Calcutta School of Tropical Medicine and Dr. W. P. Jacocks of the Rockefeller Foundation were also present.

(1) It was considered that the increase in the cases of poisoning was probably only apparent, as reports of deaths after treatment were being more frequently received since the issue of a circular by the Director of Medical and Sanitary Services at the end of the previous year requesting that all deaths should be immediately reported by telegram.

(2) At the time of the conference eight deaths had resulted out of about one and a half million persons given treatment, i.e., about one death per 150,000 treated.

(3) It was decided that, (a) the bulk of the deaths occur after combined treatment, but the symptoms incriminate oleum chenopodii; (b) the dosage of oleum chenopodii given allows a large margin of safety for a healthy person and variation in ascaridol content is of minor importance; (c) there was no need to change the dosage.

(4) Although there is no evidence to show that a condition of fasting has any direct bearing on deaths, it was felt that a light morning meal is desirable.

(5) In all the cases reviewed, it was found that the person treated was an unhealthy subject, but there was no one condition common to all the cases.

(6) It was felt that medical officers and apothecaries should pay special attention to the general condition of the patient and whenever necessary should improve the general condition before giving treatment.

(7) It was noted that no cases of poisoning in the series occurred in mass treatment administered by dispensers.

Action taken.—It was decided that, in the case of patients seeking outdoor treatment, a light morning meal is desirable about 2 hours before hookworm treatment. It was considered that special attention should be paid to the general condition of the patient, which should be improved whenever necessary before treatment.

The anthelmintics used during the year were oil of chenopodium, carbon tetrachloride, and tetrachlorethylene. When the present stocks of carbon tetrachloride are exhausted tetrachlorethylene will be used instead.

The good effect of the campaign is shown by an improvement in the general health of the people. That the people themselves realize this is evidenced by the fact that they now readily take the treatment, and sometimes even demand it.

[The above abstracts only touch on the principal diseases prevalent in the island, but the report contains many other sections indicating that all aspects of public health such as maternity and child welfare, better housing and feeding of the people, etc., are all receiving close attention and are being dealt with as energetically as funds will allow.]

THE ROCKEFELLER FOUNDATION. ANNUAL REPORT, 1934

PROGRESS IN YELLOW FEVER CONTROL

IN the fight against yellow fever it seems likely that a stage has now been reached where the old-time devastating epidemics are a thing of the past whose recurrence can be controlled. Long ago the predilection of recognized yellow fever for dogging the pathways of commerce was clearly recognized. The chief centres of havoc were the tropical seaports and river ports. In temperate zones yellow fever appeared as a warm weather epidemic in cities visited by infected ships. The outstanding epidemics of the past occurred when wooden sailing ships carried crews part of whom were suffering from yellow fever and at the same time not only transported the yellow fever mosquito but also gave it a chance to breed in the ships' water casks.

The entire campaign against yellow fever in the early days centred on an attack against the stegomyia mosquito (*Aedes aegypti*), recognized as the carrier of that disease.

The Rockefeller Foundation, from July 1925 to April 1934, maintained a field laboratory for yellow fever at Lagos, Nigeria. As a result of work originating in this laboratory it was confirmed that the black races of Africa had a type of yellow fever in which only a very small proportion of the infected persons suffered severe, clinically recognizable attacks. It was recognized that the widespread immunity of natives was probably due to the presence of yellow fever in a mild form. These milder cases could not be recognized until suitable diagnostic laboratory tests had been elaborated. It has now become clear that the great majority of cases, among both black and white races, may be quite mild, but they nevertheless give immunity to the person attacked. Moreover, these mild cases are capable of infecting the mosquito, and the mosquito in turn can infect additional persons.

Formerly it was not a simple matter to diagnose correctly mild cases of yellow fever, and it is still difficult to do so during the illness. The availability of the mouse for use in tests for acquired immunity has now made it a comparatively simple matter to ascertain whether a person has had yellow fever or not.

This so-called protection test has been applied not only to retrospective diagnosis, but also to the larger task of discovering areas in which yellow fever has occurred or is likely to occur. By limiting the test to young people and children, some notion can be gained as to how long ago yellow fever was present.

As a general result of these technical methods, which we owe to the laboratory, it has now become evident that there are two great endemic areas of yellow fever in the world. The boundaries of these areas have been approximately established. One of them occurs in Africa and extends from Senegal in West Africa to the upper reaches of the Nile. The other occurs in South America and occupies practically the whole of the Amazon Valley, reaching for short distances into other watersheds. Thus for the first time in history we can envisage with a certain degree of exactness just how large these regions are and exactly where they are located. It is something to know where we must look for the enemy.

Jungle yellow fever.—It has come to be recognized that yellow fever may exist, not only in a mild and almost unrecognizable form, but also in forms not associated with its recognized carrier, the stegomyia mosquito. The disease is transmitted and perpetuated in certain endemic areas by vectors different from the single one (stegomyia mosquito) encountered in Habana, Panama, and epidemic cities in general. Within these endemic areas, large parts of which are covered by jungle, there occurs yellow fever not carried by that mosquito and therefore offering to the scientific investigator new and as yet unsolved problems.

Since the strict correlation between the yellow fever mosquito—*Aedes aegypti*, or stegomyia—and yellow fever can no longer be maintained, we now have some inkling of the reason why complete elimination of yellow fever from the large cities through destruction of mosquitoes was not necessarily followed by the disappearance of the disease from tributary rural areas.

The factors responsible for the persistent endemicity of jungle yellow fever are as yet unknown.

Keeping yellow fever down.—By means of precautionary measures and intensive anti-mosquito work and through governmental quarantine restrictions, yellow fever has been kept successfully away from most of its old haunts in the Americas, despite the fact that the danger of bringing the disease from an endemic area into one not infected has recently been increased by the greater speed of travel. This new danger has been counteracted by rigid mosquito control work in some of the tropical cities visited by airplanes and ships, and by the International Sanitary Convention for Aerial Navigation of the Office International d'Hygiene Publique which ten nations have already ratified.

Another branch of the control service concerns the collection of liver specimens from fatal cases of brief febrile disease. This service has been greatly aided by the invention and general adoption of an instrument known as the viscerotome, which facilitates the collection of liver specimens.

Although an outstanding recent development has been the discovery that yellow fever may be benign in character, it should not be concluded from this that all the strains of yellow fever virus are benign, or that the disease is slowly dying out by becoming attenuated. This is contradicted by the simple fact that occasional fatal cases appear in regions where the protection tests indicate the presence of yellow fever. These fatal cases might never be discovered except for the viscerotome procedure of routine collection of liver specimens from all persons who die suddenly from febrile diseases. Moreover, the light cases spread yellow fever and keep it alive in areas from which it may be thought to have been eradicated by means of control measures.

Before the partial perfection of a vaccination method, first applied to human beings on 13th May, 1931, one of the tragedies of yellow fever work was the comparatively great danger to laboratory workers and men engaged directly in the fight against yellow

fever. Fortunately this danger seems to have been ended by the timely application of a method of vaccination which consists in administering modified virus accompanied by immune serum.

Intensive laboratory activity is now in progress in an effort to improve the present method of vaccination so that it can be applied to larger populations. In the laboratory of the Rockefeller Foundation no vaccination has been done without the use of human immune serum. Up to the present, although limited in application, this is still considered to be the only entirely safe method of vaccination.

Vaccination, even if extended, will in all likelihood continue to be only one line of defence. Of equal importance is the warfare directed at the eradication of the yellow fever mosquito. Above all there must continue the ceaseless efforts to penetrate farther into the mysteries of yellow fever, especially when, in its ultimate fastnesses, we are confronted with the disease in the absence of *stegomyia* mosquitoes.

MALARIA WORK

The Rockefeller Foundation engaged in anti-malaria activities in order to meet a problem which, next to that of hookworm disease, must be reckoned with in any programme aiming at a complete health service in tropical or temperate climates. Like hookworm disease, malaria is a debilitating disease. Under normal conditions, provided quinine is available, malaria incapacitates rather than kills. The use of quinine dates back several hundred years and has done yeoman service in preventing loss of lives. But it requires more than a drug to wipe out the source of malaria, which, when all is said and done, is the *Anopheles* mosquito.

The anti-malaria activities in which the Rockefeller Foundation has participated have therefore always taken the form of anti-mosquito work. These activities have in each case been based upon preliminary surveys of the area in which it was sought to control malaria. These surveys and the experiments based upon them have tended only to emphasize the variety of means which must be employed if malaria is to be successfully eliminated from any given area.

No attempts have been made in the activities of the Rockefeller Foundation to banish or eliminate malaria altogether from any country or state. Such a task involves united effort on the part of all communities, seconded by government regulation, so that the work of attacking the malaria mosquito, by whatever means or combination of means has proved to be most efficacious for the areas in question, can go on year after year until the mosquito index can be maintained indefinitely at zero.

Over and above the practical results obtained in malaria work in Italy there has been at least one major contribution in malaria research. The intensive study devoted to *Anopheles maculipennis* has led to the discovery that this species is composed of at least six varieties of mosquitoes, alike in form and shape but different in habits and environmental preferences. These varieties can be distinguished one from the other only by the circumstance that they lay different kinds of eggs. A minute study has been made of these mosquito eggs which are now used as the basis of the new classification. This biological difference in the varieties of *Anopheles maculipennis*, the malaria mosquito of Europe, has finally thrown light on the erratic distribution of malaria in Europe which heretofore had been a puzzle to malariologists. Certain varieties of *Anopheles maculipennis* prefer to feed on animals, and as agriculture has advanced they have become entirely zoophilic. Thus, although the malaria mosquito is widespread in Europe, its presence does not necessarily mean the presence of malaria. Anti-larval work enters a new phase by this discovery, which enables malariologists to give increased and more intelligent attention to the different varieties of *Anopheles maculipennis*. It is necessary to pay attention not only to the different species of *Anopheles*,

several dozens of which may transmit malaria, but in one case at least that of the *Anopheles maculipennis* of Europe, to six separate non-interbreeding varieties, each presenting problems of its own.

HOOKEWORM DISEASE AND OTHER DISEASES

The publicity centering around early hookworm campaigns had made many communities public health conscious. It put them into the correct frame of mind for doing something also against malaria and other widespread diseases. It served as an impulse to many types of health welfare work. Above all it stimulated the growing demand for better rural health departments.

Two illustrations of how hookworm work has successfully broadened out into more general public health work are afforded by Columbia, South America, and Ceylon.

In Ceylon, judged on its own merits and without reference to its general influence, the hookworm campaign might be considered disappointing in that the disease still remains one of the important causes of death. However, hookworm control work in Ceylon has had a powerful effect in Eastern countries in demonstrating in clear-cut fashion that it is possible to do successful health work of a modern type throughout the Orient. The disease itself has not yet been completely controlled, but in its connection with other diseases many human lives have been saved because of the new health habits and procedures such as health surveys initiated in the hookworm work. Throughout Ceylon the health units, which were an outgrowth of the hookworm campaigns, are making steady progress and exerting their influence not only in this island but in sections of the mainland of India and in other countries of Asia. The health units of Ceylon have become visiting centres much studied by health officials whose work lies in these areas and who obtain inspiration from the cumulative and steady progress of the Ceylonese public health work developed from the early hookworm activities.

In most countries where hookworm campaigns have at one time or another been carried on, this work has become merged with the general public health programme. Hookworm activities constitute one unit in the broader type of effort that to-day characterizes government health services. In a sense, therefore, the support which the Rockefeller Foundation now gives to local health demonstrations may be considered an extension of the former hookworm disease work.

Other diseases in which the Foundation has supported studies during 1934 are yaws, tuberculosis, diphtheria, smallpox, and undulant fever. The work in yaws centres chiefly in Jamaica, where investigations dealing with control measures and epidemiology are going forward. Definite plans of control for use in endemic areas have been formulated and are in operation. Special studies have been published dealing with a possible insect vector of yaws, a small fly, *Hippelates pallipes*.

Laboratory headquarters for tuberculosis work receiving Foundation support are situated in Cornell University Medical College. Studies in two rural areas in the United States have been made, and localized campaigns are under way in Jamaica and Austria. Chief operations centre in Jamaica where the government has been active in promoting tuberculosis work. The Foundation has been of aid in supplying an x-ray laboratory and in supporting field studies, with the object of learning more of the prevalence and epidemiology of tuberculosis in Jamaica. Throughout the tuberculosis work the emphasis has been on epidemiology.

An important study in diphtheria immunization was aided in the district of Eisenstadt, Austria. Studies on undulant fever which have for a number of years been conducted with Foundation aid in France are now drawing to a close. Additional miscellaneous studies

were published during 1934 in connection with milk sickness and intestinal amœbiasis.

[This abstract only covers about one-fifth of this extremely interesting report and although the other sections especially that of 'Medical Sciences' are of interest, we regret we have not space to spare for their abstraction.]

ANNUAL REPORT OF THE MEDICAL OFFICER IN CHARGE, HEALTH UNIT, PARTABGARH, FOR THE YEAR 1935

Introduction.—The health unit, Partabgarh, was started on 18th July, 1932, by the Department of Public Health, United Provinces, with the assistance of the Rockefeller Foundation (U. S. A.) and the Indian Red Cross Society (Provincial Branch). It covers an area 40 square miles in extent and contains a municipality, two town areas and 53 villages. The population, according to a survey made in 1933, is 36,530 (7,497 urban and 29,033 rural). The area is well supplied with roads. The soil is clayey and subsoil water level is low, being from 30 to 60 feet below the surface of the ground. Agriculture is the chief occupation of the villagers who are mostly illiterate and whose standard of living is poor.

Reporting births and deaths.—In addition to the usual reporting agencies (the public and the sweepers in towns and the choudkars in villages) the members of the staff (the sanitary inspectors, health visitors and the midwives) who collected the figures independently also submitted their reports to this office. It was found that while in Partabgarh town there occurred 179 births the 'Bakhshi' recorded 174. Similarly in Katra town the 'Bakhshi' recorded 95 deaths although the actual figure was 100. In case of Bela the reporting by the public was much less satisfactory, only 298 births being reported to the registration clerk out of a total of 445. In case of villages the reporting was even worse, only 647 births being registered in the police returns in place of 1,182, the correct figure. The percentage of births actually reported was thus 66.96 in case of Bela municipality and 54.74 in case of the villages. The percentage of omissions in the health unit as a whole was 36.31 in case of births and 42.99 in case of deaths.

Cholera.—On 25th July, a case of cholera was reported from village Pura Mohan. The source of infection could not be definitely traced. The anti-cholera measures taken consisted of isolation of patients in their homes, permanation of wells, administration of essential oils' cholera mixture, a vigorous campaign of inoculation, disinfection of floors with lime, burial of excreta underground, advice to the people about prophylactic measures and disinfection of infected material.

The epidemic was of a rather virulent type and, before it could be effectively controlled, two more villages were infected. The total number of seizures was 49 and of deaths 10. Four hundred and ninety-two anti-cholera inoculations were performed.

Plague.—No cases of deaths from plague were reported during the year. The juniors helped in trapping and destroying 936 rats.

Smallpox.—Smallpox was prevalent during five months of the year. There were no cases during the months of January, June, August, September, October, November and December. The highest incidence, 4 seizures, was recorded in March. The total number of seizures was 12 and of deaths 1. Special attention was paid to vaccination and re-vaccination of school children. The sanitary inspectors also did vaccination work. A detailed report will follow in due course.

Malaria.—The five anti-malaria centres were maintained as before. The amount of cinchona used during the year was 301 lb. 8 oz. and of plasmoquine 1,760 tablets.

General.—As a prophylactic measure against rabies 1,079 stray dogs were poisoned with strychnine.

HEALTH EDUCATION

Talks, lectures and demonstrations with the help of cinema, magic lanterns and posters were given during the year in clinics, schools, market places, fairs, meetings of co-operative societies, adult schools and other gatherings. Gramophone records on health topics were also utilized in connection with hygiene publicity work.

CONCLUSIONS AND GENERAL REMARKS

An appraisal of the Partabgarh health unit, which completed its first three years in July 1935.

(a) Maternity and child-welfare work

Work amidst the rural population was by no means easy. There was definite opposition on the part of the indigenous *dais* (midwives) who thought that their livelihood was going to be lost. The conservative women folk were none too keen to avail themselves of the services of the qualified staff during normal labours. In the early days, no information about labours was given by the people to the midwives. In some cases, the midwives, most of whom were Christians, were not permitted entry into the village homes. There were instances in which pregnant women even left the health unit to escape being attended (during confinement) by the workers of the new organization which was closely associated with an American Foundation. The staff had to gradually work its way, fighting conservatism, prejudice, ignorance, suspicion and apathy. All the indigenous *dais*, 278 in number, have been trained in the elements of clean midwifery and some of them have been provided with outfits. To-day they are a valuable asset to the health unit. Their training constitutes one of the lasting achievements, the credit for which goes to the present Director of Public Health of the province, Rai Bahadur Dr. K. L. Chaudhri, under whose instructions the work of training was taken up. The health unit staff has won the confidence of the rural population and is quite popular. The midwives are now called in in over 65 per cent of the labour cases. The poorest mother in the farthest villages to-day is ensured the facilities which are usually available to women in large towns only and at considerable expense.

At the clinic centres facilities are provided for weighing of babies, treatment of minor ailments, vaccination against smallpox, examination of urine of ante-natals, training of 'little mothers' and indigenous *dais*, group instructions and demonstrations to expectant mothers in the hygiene of pregnancy, aseptic midwifery, infant care and mother craft. A highly qualified lady doctor is in attendance to examine, advise and prescribe.

(b) Prevention and control of communicable diseases

The percentage of population immunized against smallpox is far greater than that in any other similar area in the province.

For control of epidemics there is an efficient trained staff which can be mobilized at short notice.

(c) Hygiene publicity

Popular health education has been carried out by almost all the known methods and the message of health conveyed into individual homes. Through the large maternity staff it has been possible to reach the female section of the population and to tackle ignorance and prejudices at their very roots. Never before the inauguration of the health unit was such a large section of this important group reached by the health staff.

(d) Vital statistics registration

The recording of vital statistics in the health unit is far more satisfactory. The records of 1935 indicate that the village 'choudkars' did not report as much as 45.25 per cent of births in the villages.

(e) *Rural medical relief*

The 38 village medicine chests afford facilities for the treatment of common ailments of women, children, school population and the public generally throughout the area. Through the anti-malaria centres facilities for treatment of that common and debilitating disease have been extended to villages.

(f) *School hygiene*

Health activities on an intensive scale have been started in all the schools in each of which a Junior Red Cross Group exists and 'detailed' medical inspections are carried out.

[A large number of distinguished health authorities have visited this unit and their remarks quoted here and there throughout the report are highly commendatory. We have deleted these as not being strictly germane to the subject-matter of the report itself.]

TRIENNIAL REPORT ON THE WORKING OF THE CIVIL HOSPITALS AND DISPENSARIES IN THE MADRAS PRESIDENCY FOR THE YEARS 1932 TO 1934

Number of hospitals and dispensaries.—The total number of medical institutions of all classes working in the Presidency at the beginning of the triennium under report, viz, on 1st January, 1932, was 1,337 while at the close of the triennium, viz, at the end of 1934, it was 1,356. The total number of institutions of all classes opened during the year 1934 was 27 of which 11 were local and municipal, 1 was private non-aided and 15 were rural dispensaries. The number of institutions that were closed during the year 1934 was 6, of which 1 was State special, 1 local and municipal, 1 private non-aided and 3 rural dispensaries. The number of State-public institutions working at the beginning of the triennium was 192 while at the end of the year 1934 it was 191. The number of State-special institutions was 34 at the end of the previous triennium, while the number at the end of the present triennium was 28.

Rural medical relief—Opening of subsidized rural dispensaries.—As the scheme has not been extended, but on the other hand curtailed to a certain extent, the triennium under report does not show any improvement under the subsidized medical relief scheme in rural areas.

Leprosy.—The anti-leprosy activities increased greatly during the years 1932, 1933 and 1934 as the result of the working of the group leprosy scheme sanctioned by the Government. The campaign under the direction of the chief leprosy officer developed in various directions chiefly due to the willing co-operation of the medical officers, the public and the financing bodies.

Clinics.—Leprosy clinics have been opened in all the Government medical institutions. The local boards, appreciating the useful work done to lepers, sanctioned amounts for opening clinics in the medical institutions under their control. The number of clinics that worked in 1932 was 219, in 1933, 322 and in 1934, 408. The bi-weekly attendance was above 50 in 48 clinics and above 100 in 12 clinics.

Results of treatment.—Several of the patients who persevere in treatment for a sufficiently long time are considerably benefited by the treatment. The cutaneous cases with a high concentration of the acid-fast bacilli respond very well to the esters *cum* oil mixture treatment.

District leprosy relief councils.—A striking feature in the leprosy campaign is the formation of the district leprosy organizations in accordance with the resolutions of the Calcutta and Madras Leprosy Workers' Conference held in 1933 with a view to maintaining sustained anti-leprosy activities in each district. Sixteen leprosy councils have been formed in the districts. These councils maintain a fund consisting of

contributions from local boards, donations, subscriptions, leper day collections, proceeds from benefit performances, etc., for leprosy work in the district.

The success of the leprosy campaign in the Salem district is due to the activities of the bands of social workers organized by Mrs. Todd. The success in the district was so marked that it was considered whether the experience gathered therein could not be utilized in other districts as well. The Government on the recommendation of the Surgeon-General therefore sanctioned in July 1933 for a period of six months in the first instance a scheme of anti-leprosy campaign in the districts of Chingleput and South Arcot where the incidence of leprosy is high. The campaign was organized and social work commenced by Mrs. Todd with the assistance of Mr. Curtis, assistant director of survey, as her secretary. Leprosy work needs persistent supervision and sustained zeal for development and continuance. As a result of the campaign conducted by the social workers 27 clinics were opened in South Arcot district. A leprosy day was held on 27th September, 1933, and a sum of Rs. 11,536-13-5 was collected. The results produced by Mrs. Todd and her secretary Mr. Curtis in the South Arcot district were very creditable and highly encouraging and indicative of hard work and able organization. As similar results were expected in Chingleput district the continuance of the scheme by the social workers was extended up to 31st March, 1934. The expectation has been justified.

As a result of the campaign in Chingleput district, local committees were formed in about ten places and the existing local committees were reorganized and revived. The duties of these committees are propaganda, visiting leprosy clinics and patients and helping the local clinics by collection of funds. Many members of the local committees made their clinics in the district ideal ones. This is largely due to the influence of the social workers. There has also been an increase of 30 per cent in the number of clinics as well as in the number of patients treated. The popularity and efficiency of the clinics has gradually increased. In view of the wide prevalence of leprosy in the Presidency and the need for isolating and providing proper treatment for those early infectious cases which demand hospital care, it was considered essential to increase the inpatient hospital accommodation. The admission of 100 more children into the Lady Willingdon Leprosy Settlement, Chingleput, was therefore approved.

The continuance of the scheme of social workers was further extended up to 1st April, 1935, the work being confined to the Salem district, as it was decided that the work already done in that district should be consolidated before the scheme in Chingleput district and South Arcot district could be dealt with similarly or extended to other districts.

As a part of the scheme of the district leprosy relief work in Salem district, the council has resolved to establish a home for untainted children in the district. Such a home should go a great way towards safeguarding the children of poor leprous parents from infection. The British Empire Leprosy Relief Association, Indian Council, New Delhi, on the recommendation of the Madras Provincial Committee for leprosy relief have resolved that the grant of Rs. 1,000 provided to the district leprosy relief council, Salem, for 1934 be paid to that council and that in addition a further grant of Rs. 2,000 per year for three years be made for expenditure on the proposed children's home in Salem district. The work of the district leprosy council, Salem, shows that great pains have been taken by the social workers in stimulating public interest in the campaign to eradicate leprosy.

Mrs. H. C. Buck in Saidapet has also been doing very useful work in completing a survey of the whole of Saidapet at which place 456 cases were detected in a population of 33,000. Mrs. A. Kuriyan also took a keen interest in the leprosy work in Madras City.

She obtained funds by holding a leper day and was instrumental in opening two private clinics.

Some clinics have social committees for attending to the needs of the clinics. In some clinics the medical officers have been very enthusiastic in affording relief to the lepers and have induced the public to arrange for the construction of clinic sheds and for the feeding of the indigent lepers on treatment days.

Tuberculosis.—The total number of patients suffering from tuberculosis of the lung as well as from other tuberculous diseases treated during the year 1934 was 66,478 with 1,048 deaths as compared to 59,899 with 1,008 deaths in 1933 and 59,106 with 917 deaths in 1932.

The total number of patients treated in the Government Tuberculosis Institute, Madras, during the year 1934 was 9,226 which exceeds the number of patients treated during the year 1933 by 835. The daily average attendance in 1934 was 158.02 which is 16.16 more than the daily average number in 1933. The total number of patients treated in the Government Tuberculosis Hospital, Madras, during the year 1934 was 704 with a daily average number of 80.32 as compared to 817 with a daily average number of 88.72 in 1933 and 826 with a daily average of 88.60 in 1932. The total number of deaths during the year 1934 was 13. The fall in the total number of patients treated in the Tuberculosis Hospital, Madras, during the year 1934 as compared to the previous years is partly due to the longer stay of the patients in the hospital. It is observed that the prevalence of tuberculosis is most between the ages of 15 to 24 years and 25 to 34 years, i.e., during the active period of life. Of the 704 cases treated in the Tuberculosis Hospital, Madras, 532 were cases of pulmonary tuberculosis while the remaining were either non-tuberculous affections of the respiratory tract or extrapulmonary tuberculosis cases.

The treatment of tuberculosis is still in its infancy in this Presidency as regards the provision of beds in special hospitals or sanatorium dispensaries and clinics. A sanatorium on the lines of that at Madanapalle is

needed in various groups of districts within easy distance of the largest towns; one is badly needed outside Madras. A sanatorium is proposed at Perundurai some 48 miles from Coimbatore and local efforts are well advanced in this direction.

Medical education.—Considerable improvement was effected in the matter of medical education in this Presidency during the triennium. The recommendation of the Medical Education Committee appointed by the Government that medical education should be centralized in Madras and Vizagapatam has been given effect to by closing the medical school at Tanjore from 1st May, 1933. Admissions to the medical school, Tanjore, were stopped in July 1932, the students from the school being transferred to the Stanley Medical School, Madras. The L.M.P. course has been extended to five years to enable the students to have sufficient scientific knowledge and clinical experience before they pass out of the schools, and to anticipate their hopes for inclusion in a common medical register. The curriculum of studies has also been revised. The percentage of pass marks for the five-year course students in all board examinations prior to the final qualifying examination has been revised in conformity with the standard of the General Medical Council of the United Kingdom. It is noteworthy that it has been possible to admit a class of students possessing better preliminary educational qualifications. With the introduction of the five-year course for the L.M.P., the school laboratories have been brought up to the requisite standard.

The year 1934 was marked by an epoch-making event in the history of Indian medical education. The primary fellowship examination of the Royal College of Surgeons of England was held at Madras in December 1934 for the first time in India. It is a matter of gratification that many of the Madras students came out successful in their first attempt. Out of 60 candidates appearing for the examination, 21 were successful—of whom 13 belong to Madras.

LATE REACTIONS AFTER ANTI-CHOLERA INOCULATION

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—During the last cholera epidemic in the Bassi district, Patiala State, mass anti-cholera prophylactic inoculation was done. There was a general and a local reaction which lasted for two or three days following the inoculations.

About 8 to 10 per cent of the persons inoculated got another general and local reaction on the 12th, 13th or 14th day of the inoculation, in the usual form of a pyrexia (varying from 100°F. to 102°F.) and local redness at the site of the injection along with pain and tenderness. But this secondary reaction, if I may so call it, was milder in type than the primary one. No other sign or symptoms were observed. This secondary reaction lasted for about 28 to 36 hours only. Many of the sturdy villagers did not care at all at its appearance and thus got no treatment for it, while others who came to us for advice were treated on general lines and symptomatically.

The only possible explanation that I could think of at that time was that it might be due to an abscess formation due to negligence on our part of not adopting sufficiently rigid aseptic technique. But, out of the four thousand inoculations done by me in that part of the district, only one of them developed into an abscess on the sixth day. We had taken every possible aseptic precaution throughout and the vaccine which was supplied by the Central Research Institute, Kasauli, was used within two or three days of its receipt.

I consulted my other colleagues who too were working in the other cholera-stricken areas of the State about it and all of them also observed the same phenomenon. A fruitless search of all the available literature on the subject was made to know the cause and significance of this secondary reaction after the prophylactic anti-cholera inoculations.

I would like to know if others have observed this secondary reaction in their practice, and if they can enlighten me as to its possible cause and significance.

Yours, etc.,

MADAN TEWARI, M.B., B.S.
Honorary Clinical Assistant.

RAJINDRA HOSPITAL,
PATIALA (STATE).

TREATMENT OF CHRONIC DIARRHŒA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Though I myself doubt whether the following is worth publishing in a medical paper, while discussing treatment of chronic diarrhœa, my friends were greatly impressed with my experience and pressed me to report it in your valued journal.

Some five years back—I was then in Karachi—I suffered from sprue (?). I took parathyroid and calcium, emetine injections, Taka-diastase, fresh liver—by mouth, Anabin, etc., without any effect. This went on for six to seven months. I used to get six to seven large motions per day. Then in the hospital I found

a sample box of Ultracarbon (Merck). As per instructions I took two teaspoonfuls per day—one after each feed. From the first day, uneasiness and sinking feeling was much better. On this, I stopped every drug and persevered with Ultracarbon and milk diet for three to four months. By this time I was practically all right and gradually reverted to normal diet.

Yours, etc.,

K. J. MANDKANI, D.O., M.B., B.S.

SIR J. J. HOSPITAL,
BYCULLA, BOMBAY,
17th February, 1936.

INTESTINAL TUBERCULOSIS

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I must compliment Dr. Shrikhande for his very comprehensive article on intestinal tuberculosis which appeared in the February issue of the *Gazette*. One thing is not clear to me. It appears that he is optimistic about our present-day means of diagnosing this condition early. But I must confess that, even after going through his article very carefully, my difficulties remain the same as before.

Regarding early symptoms he mentions nervousness, slight impairment of appetite and constipation as the most useful diagnostic triad. It is a matter of common knowledge that impairment of appetite and constipation are usual symptoms of pulmonary tuberculosis. Nervousness can hardly be considered as a dependable symptom. Persistent diarrhoea and tenderness over abdomen are of definite diagnostic value but unfortunately they appear rather late.

As regards laboratory methods the writer himself admits that the presence of tubercle germs in the stool by itself is of little significance. Perhaps it is not unreasonable to think that the presence of pus and blood in the stool is of little guidance in a tropical country where different kinds of colitis are so very common.

Radiological diagnosis appears to be the most dependable according to the writer, as well as other workers. Evidently it depends on the hyper-motility of intestines due to tuberculous ulcerations. Under the heading 'Symptoms', the writer mentions that ulcerations in the small intestines which occur early cause constipation. Perhaps it is reasonable to infer that a lesion which causes constipation is not likely to hurry over the barium meal indicating hyper-motility. If that be the case it is doubtful if x-rays be of any use to detect early lesions in intestines. Even when hyper-motility is shown by x-ray examination due to extension of ulcerations to caecum and colon, have we got means to ascertain radiologically whether such hyper-motility is due to tuberculous lesions or to other forms of colitis commonly found in tropical countries? A tuberculous patient is not immune from colitis due to other causes.

For these reasons I am at a loss to understand how we have materially advanced in the matter of diagnosing this condition early. However, I will feel obliged if Dr. Shrikhande kindly throws more light on the issues raised herein. As a general practitioner, like others, I face these difficulties every now and then.

Yours, etc.,

A. ROY CHOWDHURY, B.Sc., M.B.

THE FEEDING OF INFANTS IN INDIA

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I would ask you to be good enough to correct an omission in my article on the feeding of children published in the January 1936 number of the *Indian*

Medical Gazette under the heading Cow and Gate, page 6.

I understand that to the export brand of Cow and Gate is now added a natural concentration of vitamin D in approved quantities, namely Vitex. Under the heading Cow and Gate therefore the Vitamin Content should read as 250/300 International units per pint and no other form of vitamin D need be added.

Yours, etc.,

E. H. VERE HODGE, M.D. (Cantab.),
LIEUTENANT-COLONEL, I.M.S.

MEDICAL COLLEGE,
CALCUTTA,
10th March, 1936.

Service Notes

APPOINTMENTS AND TRANSFERS

THE Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal Staff:—

Colonel H. C. Buckley, to be Honorary Surgeon, *vice* Major-General E. W. C. Bradfield C.I.E., O.B.E., vacated. Dated 21st December, 1935.

Lieutenant-Colonel M. G. Bhandari, Superintendent, Yeravda Central Prison, is appointed to officiate as Inspector-General of Prisons, Bombay Presidency, *vice* Lieutenant-Colonel E. E. Doyle, proceeding on leave.

Lieutenant-Colonel R. V. Martin, on return from leave, is appointed to officiate as Inspector-General of Prisons, Bombay Presidency, *vice* Lieutenant-Colonel M. G. Bhandari, reverting.

Lieutenant-Colonel M. G. Bhandari, on relief, is appointed to be Superintendent, Yeravda Central Prison, *vice* Mr. D. N. Chiplunkar, reverting.

Lieutenant-Colonel R. Hay, an Agency Surgeon, is appointed as Civil Surgeon, Ajmer, and Chief Medical Officer in Rajputana, with effect from the afternoon of the 19th December, 1935.

Lieutenant-Colonel W. J. Webster, M.C., Officiating Assistant Director, Central Research Institute, Kasauli, is appointed to officiate as Director of that Institute, in addition to his own duties, *vice* Lieutenant-Colonel J. Taylor, granted leave.

The services of Lieutenant-Colonel C. de C. Martin are placed permanently at the disposal of the Government of Burma, with effect from the 20th June, 1932.

The services of Captain D. K. L. Lindsay are placed temporarily at the disposal of the Government of Burma, with effect from the 17th December, 1935.

The services of Captain C. K. Lakshmanan are placed temporarily at the disposal of the Government of Bengal, for appointment as Port Health Officer, Calcutta, with effect from the 10th February, 1936.

The services of Captain M. Jafar, an officer of the Medical Research Department, on foreign service under the Indian Research Fund Association, are placed temporarily at the disposal of the Government of Madras, for appointment as Officiating Assistant Director, King Institute of Preventive Medicine, Guindy, with effect from the date he assumes charge of his duties.

PROMOTIONS

Major to be Lieutenant-Colonel

J. E. Ainsley. Dated 29th December, 1935.

The provisional promotions to the rank of Major of the undermentioned officers are confirmed:—

A. Tait.
G. P. F. Bowers.
J. S. Riddle.
J. E. Gray.

S. Smyth.
M. H. Wace.
R. L. Frost.
J. C. Drummond.
D. M. Fraser.
J. F. Shepherd.
K. S. Fitch.
S. C. H. Worseldine.

Captain to be Major

G. J. Joyce. Dated 22nd December, 1935.

LEAVE

In supersession of previous notification, Lieutenant-Colonel E. E. Doyle, C.I.E., D.S.O., Inspector-General of Prisons, Bombay Presidency, is granted leave for 8 months, from the 22nd February, 1936, or any subsequent date of relief.

Major R. S. Aspinall, an Agency Surgeon, is granted leave on average pay for 3 months combined with leave on half-average pay for 4 months and study leave for 3 months, with effect from the afternoon of the 19th December, 1935.

RETIREMENT

The undermentioned officers retire:—

Colonel C. A. Gill. Dated 12th August, 1935.

Lieutenant-Colonel J. D. Sandes. Dated 22nd December, 1935.

Notes

BOMBAY OBSTETRIC AND GYNÆCOLOGICAL SOCIETY

At a clinical meeting of the Bombay Obstetric and Gynæcological Society held at the rooms of the Bombay Medical Union, Lieut.-Colonel Spackman said that the menopause marked the termination of the reproductive stage of a woman's life and cessation of menstruation was usually the most prominent and sometimes the only clinical manifestation.

Dealing with the treatment, he said that encouraging the patients to take interest in the household, social and other outdoor activities, which took their minds off their worries, had beneficial results. There were some cases which needed some form of active treatment. Pelvic diathermy, massage, visits to health resorts and spas were more useful for their unbalanced minds than for any real organic change. Among the drugs bromides and valerian well deserved their traditional reputation. The opium group should be avoided. Insomnia can be treated by sedatives of the barbiturate series like luminal. A definite course of these remedies was better than intermittent and irregular use. Organotherapy results were unsatisfactory because of the great variations of ovarian hormone in the individuals and at different times in the same individuals, uncertainty of the potency of various preparations in the tropics and variations of action of the different secretions of the digestive system on these preparations. The ovarian hormones could be stimulated by x-ray and diathermy directly on the ovaries or indirectly through activating the pituitary gland. Alternative to stimulation was substitution therapy by supplying the hormone orally or by injection. Ovarian grafts either autogenous or heterogeneous were also advocated and they with different degrees of success or failure. No method was yet devised by which these grafts were kept active for a long time. Only those hormone preparations, containing folliculin secretion, which were used by injections had given good results in his hands. Of these Progynon B Oleum was found to be most effective. Yet many cases

were unaffected by its use. Complications like pruritus vulvæ and senile vaginitis were treated by folliculin hormones.

EVIPAN SODIUM

In introducing an anæsthetic that can be given by intravenous injection with the least possible preliminaries and with the minimum of qualified assistance, it would almost seem that the chemists in Elberfeld were considering India's most pressing requirement.

This preparation has already acquired a past history in this country and it has been very extensively used, but, when once it has penetrated into every dispensary and small rural hospital in India, it is assured of a very great future.

The manufacturers have prepared a very useful booklet on the technique of Evipan Sodium which we recommend to all doctors who propose to take advantage of this useful advance in anæsthetics.

The book is well written and instructions are given explicitly. The whole subject is dealt with in a scientific and systematic manner. It is the type of book that, except for the fact that Evipan Sodium is a proprietary preparation, would have been priced at two rupees or so, and would have been assured of a wide circulation. As it is, the agents in India of the manufacturers are prepared to send a free copy to any doctor interested in the subject. Applications should be made to the Haverro Trading Company, Limited, Post Box 642, Bombay.

Publishers' Notice

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

IMMUNOLOGICAL METHODS IN THE DETERMINATION OF INFECTION IN A RANDOM SAMPLE OF HOSPITAL ADMISSIONS

(PART I)

(THE FREQUENCY AND CONCENTRATION OF 'H' AND 'O' AGGLUTININS FOR THE BACILLI OF THE TYPHOID-PARATYPHOID GROUP IN 280 INDIVIDUALS ADMITTED INTO THE CARMICHAEL HOSPITAL FOR TROPICAL DISEASES, CALCUTTA)

By C. L. PASRICHA, M.A., M.B., B.Chir., M.R.C.S., L.R.C.P.
CAPTAIN, I.M.S.

G. PANJA, M.B., D.B.

and

S. LAL, M.B., B.S.

(From the Department of Bacteriology, School of Tropical Medicine, Calcutta)

RECENT studies employing immunological methods in the diagnosis of infection have conclusively shown that the occurrence of agglutinins in the serum of apparently healthy individuals can be considered as evidence of exposure to the specific infectious agent either through artificial means such as vaccination or as a result of natural infection, clinical or sub-clinical. That the incidence of antibodies against a given organism is an index of the prevalence of infection by that organism in a particular region is stressed by Topley (1933) who, after reviewing the available evidence, concludes that 'whatever may be our views with regard to the mode of origin of the "normal" antibodies there is now no doubt that the different frequencies observed in different countries, age groups, social classes, occupational groups, etc., is highly correlated with the risk of infection to which these groups are exposed. We shall, for instance, certainly not err if we draw from the fact that group A shows a 10 per cent frequency of agglutinins to bacillus X and group B a 0.2 per cent frequency, the conclusion that infection with that organism is common among the population of which group A is a sample and rare among the population exemplified by group B. It should perhaps be emphasized that the difference is the most significant point. If we found, in a large number of samples of adults, drawn from many different countries and many different occupational groups, that the frequency of a particular antibody at a particular titre was always in the neighbourhood of say 5 per cent, we should, in the present state of our knowledge, be hard put to it to determine whether this indicated uniform frequency of the infection in question, or whether we were dealing with some non-specific effect. Surveys of this kind are becoming increasingly more common, and serve

a very useful purpose. It is often important to map out infected areas from the administrative point of view, and a knowledge of the infections prevalent in his district is of considerable help to the bacteriologist faced with the diagnosis of a clinically atypical fever—from this viewpoint this particular method of survey might be exploited far more widely than it is, especially in tropical countries'.

In a country such as India where 'fevers' of so many different types and of different aetiologies exist and where facilities for the determination of the exact nature of the different pyrexias are limited it is impossible to obtain any reliable records of the incidence of the different 'fevers'. The enteric group of fevers are much more prevalent than the records indicate as most cases are included among 'fevers'. Even the incidence of these fevers in a number of the larger towns, where facilities for exact diagnosis exist, is unlikely to be even approximately correct. We have not been able to obtain any reliable figures referable to the whole of India.

The deaths and death rates from enteric fevers for Bengal are extracted below from the Bengal Public Health Report for 1930:—

TABLE I
Deaths and death rates from enteric fever

Year	NUMBER OF DEATHS			
	Province	All towns	Calcutta	Rural area
1929 ..	10,487	1,288	765	9,199
1930 ..	11,144	1,222	729	9,922
<i>Death rates per mille</i>				
1929 ..	0.22	0.41	0.71	0.21
1930 ..	0.24	0.39	0.68	0.22

'Eighteen towns returned rates above the urban average for enteric fever (0.39), the highest being registered in Hooghly, Chinsurah. No death from enteric fever was returned from 63 towns. 1.6 per cent of fever deaths and 1.07 per cent of total provincial mortality were due to enteric fever against 1.5 and 0.9 per cent in the previous year'.

It can be confidently asserted that the apparently greater incidence of the disease in Calcutta, as judged by the mortality rates, does not represent greater degree of infection in that city but is the result of better laboratory facilities and more accurate diagnosis. The statement that no deaths from enteric fevers were returned from 63 towns can only be taken to represent that no death in these towns was diagnosed as due to enteric fevers.

The Army in India has maintained very careful records of the incidence and mortality rates of enteric fevers, and up-to-date serological methods have been introduced in the diagnosis of these fevers. The following table giving the incidence and deaths amongst protected and

unprotected classes in the Army is extracted from the Annual Report of the Public Health Commissioner with the Government of India (1934).

is exceedingly small. We badly need more detailed information about the frequency and concentration of 'H' and 'O' agglutinins for bacilli of the typhoid-paratyphoid group in the

TABLE II

Showing the incidence and deaths from enteric fevers among protected and unprotected classes in the Indian Army

Group	Strength	ACTUAL		RATIO PER 1,000		Case mortality per 100
		Cases	Deaths	Cases	Deaths	
1932 .. { Protected ..	54,554	172	13	3.15	0.24	7.55
	655	16	2	24.42	0.35	12.50
Average of 5 years. { Protected ..	53,885	179.4	13.2	2.33	0.24	7.36
	1,382.4	20.2	1.8	14.61	1.30	8.91

It will be seen that the incidence of enteric fevers is high in the unprotected group of individuals. We can take the incidence in the unprotected group of individuals in the Army as representing approximately the incidence of enteric fevers in the civil population.

Immunological methods, as far as we are aware, have not been employed for the determination of the degree of infection by the enteric group of organisms in this country. As serological methods are pre-eminently suitable for conditions prevailing in India it was resolved to estimate the 'H' and 'O' agglutinins for the enteric group of organisms in sera of certain individuals admitted into the Carmichael Hospital for Tropical Diseases. At the outset, we would state that no serological methods can give such definite or such convincing data as the actual isolation of the infecting organism. When, however, the difficulties inherent in cultural methods for the detection of typhoid carriers and the expense, the organization and management of an adequately controlled typhoid-carrier survey are realized, it will be apparent that the comparatively simple tests, such as the agglutination test when properly controlled, may be expected to yield more reliable results than haphazard stool examinations. Recent works in different parts of the world where the frequency of agglutinins in samples of a community has been estimated have shown that such surveys afford an indication of the frequency and distribution of a particular infection in that community. In table III are summarized some of the published results of the frequency of agglutinins for the three principal types of the enteric group of organisms.

There are many difficulties in the interpretation of observations such as those recorded in table III. When the published data are carefully studied it will be obvious that the sum total of the evidence that has been accumulated

serum of 'normal' persons. It is established that there can occur a fall in the frequency of agglutinins among the population as a whole as a result of the 'wearing-off' of the effect of the actual disease or inoculation. There are recovered cases of typhoid fever who, although they continue to pass the organism, do not show any agglutinins in the blood. Ledingham and Arkwright (1912) record 4 out of 9 carriers who showed no agglutinins and Havens (1935) cites 3 out of 6 carriers with no agglutinins either for a stock laboratory culture or for the carrier's own strain. On the other hand there is evidence to suggest that non-enteric febrile diseases following vaccination or a previous attack of typhoid can give rise to an anamnestic reaction which is a non-specific re-stimulation of the agglutinins. Felix (1928) has shown that this non-specific re-stimulation occurs only with the 'H' agglutinins and not in the 'O' agglutinins.

We do not propose to review the great mass of literature that has grown up on the subject of so-called 'normal agglutinins'. The published evidence, such as it is, shows that, in localities where there is a high endemic rate of enteric fevers, a large proportion of the population show agglutinins for these organisms, and conversely, in localities with low incidence of these fevers, only a small proportion of individuals have these agglutinins.

The present paper records the results of the examination of sera for the presence of agglutinins for the typhoid-paratyphoid group of organisms.

Sera were obtained from 280 non-enteric patients admitted into the Carmichael Hospital for Tropical Diseases during the year 1935. The patients were all Indians and the majority of them permanent residents of Calcutta or neighbouring districts. These sera were tested against eight different antigens of the typhoid-paratyphoid group, certain strains of the proteus X group, a series of authentic dysentery

TABLE III

Note:—The titres recorded by some of the workers were different from those shown in the table, but for the sake of clarity these have been included in the nearest figures, for example if the titres recorded were 1 in 20, 1 in 40 and 1 in 80 these have been included in 1 in 25, 1 in 50 and 1 in 100. When the worker has not recorded the results with certain antigens or at certain dilutions this is shown as —.

At the bottom of this table is given the result of our own inquiry in Darjeeling and Calcutta.
Remarks:—(1) Uninoculated persons. (2) No history of previous inoculation or disease. (3) The higher percentages in the males are undoubtedly due to previous inoculation and the figures for the females represent what one may expect to find in uninoculated adults. (4) Of sixty individuals from whom accurate history was obtained, seven had been vaccinated and five had had typhoid fever. (5) Dilutions below 1 in 100 not used. Definite information as regards no previous attack in 62 out of the 100 individuals. (6) Unselected individuals not suffering from enteric fever. (7) Indigenous persons with no history of attack or inoculation. (8) Quoted by Topley (1933). (9) Accurate history could not be obtained from many of the individuals. (10) Normal individuals who had not been vaccinated and who had not had enteric fever. (11) Two of the 17 individuals were probably typhoid cases, and five had history of previous attack or were probably vaccinated. This explains the very high percentage showing agglutinins. The paucity of the numbers does not justify any conclusions to be drawn from these results. (12) Unpublished results of an investigation carried out amongst individuals of different occupational groups. (13) Unselected hospital cases suffering from non-enteric group of diseases and uninoculated.

organisms and certain selected groups of non-authentic dysentery organisms. In this present paper only the results obtained with the typhoid-paratyphoid group of organisms are recorded. To avoid unnecessary complication in the reading of results, reactions with other organisms have been omitted.

Technique.—Each serum was put up in five dilutions from 1 in 25 to 1 in 400 and was tested against the following eight suspensions of the typhoid-paratyphoid group of organisms:—

(1) Formolized broth suspensions of *Bact. typhosum*.

(2) Formolized broth suspensions of *Bact. paratyphosum A*.

(3) Formolized broth suspensions of *Bact. paratyphosum B*.

(4) Formolized broth suspensions of Hirschfeld's bacillus.

The above are 'H' suspensions containing about 500 million organisms per c.cm.

(5) Alcoholized agar-culture suspensions of *Bact. typhosum*.

(6) Alcoholized agar-culture suspensions of *Bact. paratyphosum A*.

(7) Alcoholized agar-culture suspensions of *Bact. paratyphosum B*.

(8) Alcoholized agar-culture suspensions of Hirschfeld's bacillus.

The last four are the 'O' suspensions. The test strains were examined periodically for agglutinability with standard sera and every

strain of Hirschfeld's bacillus that we employed was not sufficiently agglutinable, though it was well agglutinable by its homologous serum.

We did a comparative series of tests employing Felix's strains *Bact. typhosum* H901 and *Bact. typhosum* O901 obtained from the Lister Institute and 'H' and 'O' suspensions prepared with our standard laboratory typhosum strain. The results were parallel but the motile strain 901 was not as sensitive as the formolized suspension of our local strain. The results recorded are those obtained with our local *Bact. typhosum*. The same strains were used throughout the experiment.

The serum-suspension mixtures were incubated in a water bath at 52°C. The 'H' agglutination was read after two hours and the 'O' agglutination after about 18 hours. The readings were made with the aid of artificial light against a black background and the agglutination was read to the limit of visibility with a magnifying lens. Only clear-cut definite results were recorded. Adequate controls were maintained throughout.

When agglutination occurred in all serum dilutions, a second test was made, a greater range of dilutions of the serum being used. In all cases an end titre was determined.

Tables IV and V give a summary of the results of the examination of the 280 sera. We have grouped the patients into various age groups and sub-grouped them into two main

TABLE IV

Percentage of sera obtained from 280 individuals not suffering from enteric infection giving different type of agglutination at specified titres or higher

Organisms	SHOWING TOTAL AGGLUTININS			'H' AGGLUTININS			'O' AGGLUTININS		
	1 in 25 and over	1 in 50 and over	1 in 100 and over	1 in 25 and over	1 in 50 and over	1 in 100 and over	1 in 25 and over	1 in 50 and over	1 in 100 and over
<i>Bact. typhosum</i> ..	28.2	12.8	3.9	17.1	8.2	2.8	11.8	6.4	1.8
<i>Bact. paratyphosum A</i>	7.1	2.8	1.4	6.07	2.5	0.71	2.1	1.07	0.71
<i>Bact. paratyphosum B</i>	11.4	6.07	2.8	7.5	5.7	2.5	5.0	0.35	0.35

care was taken to maintain the cultures in the smooth phase. The antigens were prepared in bulk in amounts sufficient to last for about three months and were kept in a refrigerating machine. Thick 'O' suspensions were preserved in 66 per cent glycerine and were diluted, when required, with normal saline. The final opacity was adjusted to 1,000 millions per c.cm. The first hundred sera were tested against all eight suspensions, but as we failed to obtain any significant agglutination with suspensions 4 and 8, these were omitted from the test, leaving the three 'H' suspensions and three 'O' suspensions of *Bact. typhosum*, *Bact. paratyphosum A* and *Bact. paratyphosum B*. It is probable that the

occupational groups—labouring and non-labouring classes. In the labouring class are included menials and persons of the lower strata of life, others of a better social status are included in the non-labouring class. None of these patients had received prophylactic inoculation with any of the typhoid-paratyphoid group of organisms, so that in the present series we have not to contend with any agglutinins resulting from inoculations. Agglutinins present in the sera are the result of natural infection. Every possible care was taken to obtain a reliable history of each patient in order to exclude previous enteric infection. In a few we obtained past history of continued fevers suggestive of enteric

infection. In some individuals it was impossible to obtain satisfactory histories to exclude, with any degree of certainty, a previous enteric infection. Some of the patients at the time of collection of the sample were suffering from febrile diseases in no way suggesting enteric infections.

The individuals in our series cannot be taken to represent a sample of the normal population and indeed it would be difficult to define what would constitute a sample of the 'normal' population amongst the indigenous people of Calcutta. We have in our series of 280 individuals a 'cross section' of the type of persons seeking admission into hospital and all that we can claim for this series is that they represent a random sample of individuals admitted into hospital. We cannot apply our figures, based as they are on the examination of a series containing a number of sick persons, to the general population at large.

Only the two main groups, the labouring class and the non-labouring class (and this admittedly is a very arbitrary and in many instances an unsatisfactory method of classification), have been dealt with because the numbers of the various sub-groups are too small for any useful analysis.

The frequency of agglutinins for *Bact. typhosum*, *Bact. paratyphosum A* and *Bact. paratyphosum B* in different age groups is shown in the following graph. The actual percentages are recorded in table V.

It will be apparent that agglutinins are far more frequent for *Bact. typhosum* than for the paratyphoids. A study of tables IV, V, VI and

GRAPH I

The frequency of agglutinins ('H' and 'O' combined) for *Bact. typhosum*, *Paratyphosum A* and *B* in specified age groups.

TABLE VI

Percentage of sera giving agglutination with different organisms and in different combinations

Typhosum only	Para A only	Para B only	Typhosum and para A	Typhosum and para B	Typhosum para A and para B	Para A and para B
18.5	2.8	6.4	2.1	2.5	1.8	1.07

TABLE VII

Number of sera showing different types of agglutinins

T(H)	T(O)	A(H)	A(O)	B(H)	B(O)	T(O) + T(H)	T(H) + A	T(H) + B(H)
30	15	5	1	10	7	7	1	3

T(H) + A(H) + B(H)	T(O) + A(H)	T(O) + B	T(O) + A + B	T(H.O.) + A(H) + B(H)	A(H) + B(O)	A(H) + A(O)	B(H) + B(O)	T(H.O.) + A
2	3	4	2	1	3	2	1	2

T = *Bact. typhosum*, A = *Bact. paratyphosum A*, B = *Bact. paratyphosum B*.
The type of agglutinin whether 'O' or 'H' is indicated in brackets.

VII will show that this difference is even more marked when the actual titres of 'H' and 'O' agglutinins are compared. The 'O' agglutinins for paratyphoid A are present only in a very small percentage whereas 'O' agglutinins for typhosum and paratyphosum B are more frequent, those for typhosum being the most frequent and present in higher dilutions of serum.

In tables VI and VII are given the relative frequencies of the different types of agglutinins.

The frequency of agglutinins for the enteric group of organisms in our two occupational groups, the labouring and the non-labouring classes, is shown in table VIII. In order to simplify the reading of results we have considered a serum showing agglutinins for any of the three organisms as positive for the enteric group. Tables VIII, IX and X are based on such figures.

TABLE VIII

Showing the frequency of agglutinins for the Bact. typhosum and Bact. paratyphosum A and B amongst the labouring and non-labouring groups of individuals examined

Class	Number of persons examined	Number positive in 1 in 25 or over	Percentage positive in 1 in 25 and over
Labouring class	176	70	40
Non-labouring class.	104	29	24

In table IX and graph II is given the frequency of agglutinins for the enteric organisms in the two classes of individuals according to different age groups.

TABLE IX

The percentage of sera showing agglutinins in 1 in 25 or over in various age groups in the specified class of persons

CLASS OF PERSON	LABOURING		NON-LABOURING	
	Number of persons	Percentage positive	Number of persons	Percentage positive
Age groups				
0-10 years	9	55.5	6	0.0
11-15 "	5	40.0	15	26.6
16-20 "	19	37.0	10	30.0
21-25 "	38	29.0	17	29.4
26-30 "	41	39.0	16	31.2
31-40 "	43	44.1	17	41.1
41-50 "	16	50.0	14	21.4
51-70 "	5	40.0	9	22.2

Although for an adequate analysis a far larger number of individuals must be examined for the results to have any statistical value, the results obtained in our present series and with our somewhat arbitrary classification suggest that infection with the enteric group of organisms,

GRAPH II

The percentage of sera showing agglutinins in 1 in 25 or over in various age groups in the specified class of persons.

Age groups.

as judged by the frequency of agglutinins, is far more prevalent in the labouring class than in those of higher social status. When we compare the different age groups in our two classes of individuals the differences in the percentages are even more marked. We see that in the first decade of life there is a large percentage of individuals in the menial and labouring class who show agglutinins for the enteric organisms in their sera, and that about adult life the curves in both series meet, suggesting that a large majority of us are infected with these organisms before we reach adult life. After the second decade the curves run parallel, the individuals in the labouring class showing the greater frequency. This is indeed what one would expect and anyone familiar with the deplorable conditions under which this class of person lives would hardly expect otherwise. Conditions in the 'bustees' and other overcrowded areas where the majority of the labouring class live are ideal for the spread of intestinal infection; there are

frequent chances of faecal contamination, and the surroundings are heavily polluted with man's own excrement.

The results of the serological tests, although admittedly of limited value, because of the small numbers on which some of the percentages are based, illustrate the marked frequency of infection with the enteric group of organisms. We believe that such surveys are of more value than the search for carriers; they demonstrate that actual infection of the body has at some time or other taken place and that this infection has resulted in the active participation of the body in producing active immunity of which the agglutinins are readily demonstrable and measurable, and are an index.

In table X the frequency of agglutinins against the enteric group of organisms in males and females is given. There is no statistically significant difference in the two sexes.

TABLE X

Showing the frequency of agglutinins for the Bact. typhosum, Bact. paratyphosum A and Bact. paratyphosum B organisms amongst the different sexes in the individuals examined

Sexes	Number of persons examined	Number positive to 1 in 25 or over	Percentage positive in 1 to 25 and over
Males ..	234	86	36.7
Females ..	46	13	28.2

In table XI is given the relative frequency of enteric agglutinins in individuals suffering from diseases other than enteric fever.

TABLE XI

Showing the frequency of agglutinins for Bact. typhosum, Bact. paratyphosum A and Bact. paratyphosum B in sera obtained from individuals suffering from diseases other than enteric fever

Conditions	Number of persons examined	Number positive to 1 in 25 or over	Percentage positive in 1 to 25 and over
Splenomegaly	18	2	11.1
Kala-azar ..	9	0	0.0
Anæmias ..	12	4	33.3
Non-enteric febrile cases.	52	15	28.9
Miscellaneous, febrile cases.	166	65	38.9
Malaria ..	23	13	56.5

Although rigid conclusions are to be deprecated because of the very small numbers of the various sub-groups examined, it is obvious that there is a real need for more information on the frequency and concentration of agglutinins in

persons suffering from various febrile conditions. The complete absence of agglutinins in patients suffering from kala-azar is striking, suggesting the paralysis or blockage of the antibody-producing system. These results also illustrate that there is no increase in the agglutinins in non-enteric febrile cases as compared with the afebrile individuals. This does not support the generally accepted view, that in febrile conditions non-specific stimulation of agglutinins occurs. This point is better illustrated when the results of the qualitative-receptor analysis of individual cases are studied. It is obvious that there is no appreciable difference in the frequency and titre of the 'O' agglutinins.

In table III we gave the results of various published reports of serological surveys that have been undertaken in different parts of the world. If we accept the view that the different frequencies in the so-called normal antibodies in different countries are correlated with the risk of infection to which different individuals are exposed we must conclude that the results reported in this paper suggest a far greater degree of prevalence of enteric fevers in Calcutta than in other parts of the world where

TABLE XII

Showing the comparative percentage of agglutinating sera in the uninoculated and inoculated in samples of population in (a) London compared to that of (b) Darjeeling and (c) Calcutta

Organisms	UNINOCULATED		INOCULATED	
	Number of sera examined	Per cent positive	Number of sera examined	Per cent positive
(a) Figures from Rosher and Fielden's (1922) survey in London				
<i>Bact. typhosum</i> ..	181	3.0	149	89

<i>Bact. paratyphosum B</i>	181	4.0	149	71
(b) Figures from a survey in Darjeeling				
<i>Bact. typhosum</i> ..	85	32.0	31	84
<i>Bact. paratyphosum A</i>	85	9.0	31	64
<i>Bact. paratyphosum B</i>	85	25.0	31	84
(c) Calcutta				
<i>Bact. typhosum</i> ..	280	28.2
<i>Bact. paratyphosum A</i>	280	7.1
<i>Bact. paratyphosum B</i>	280	11.4

such surveys have been conducted. This is illustrated better in table XII which compares the results obtained in London with the results obtained in Calcutta and in Darjeeling. The figures for Darjeeling are based on an investigation carried out by one of us (C. L. P.) in 1934. Sera from 116 individuals were examined for the presence of agglutinins of the typhoid-paratyphoid group of organisms.

We have not examined any individuals in Calcutta who had been inoculated with T.A.B. vaccine. When we compare the results of our series of inoculated individuals examined in Darjeeling with a similar group in London, we find no significant difference in the results obtained, in fact the similarity of the percentages is remarkable. Of the uninoculated the percentage of those showing agglutinins for the typhoid-paratyphoid group of organisms is considerably higher in Darjeeling and Calcutta than a similar group from the frequencies obtained in London and is striking. One is irresistibly led to the conclusion that infection with these three main species of enteric organisms is far more prevalent in our sample of population than in London.

Conclusions

Serological surveys for the determination of infection in any given community are valuable. They yield useful information, are comparatively easy to conduct and are particularly suited to conditions in India where very often the laboratory is situated at some distance from the actual place where such an investigation is desired. Although considerable discrepancies exist in the opinions held concerning the relationship between so-called 'normal' and immune agglutinins, a knowledge of the type of agglutinins, whether 'H' or 'O', their frequency and concentration in individuals differentiated by age, occupation, social status and other factors would be of the utmost value and is urgently needed in India. Such surveys would be of great practical value in determining areas of endemicity and eventually in assessing the value of any preventive measures. Further, when it is realized that sub-clinical infections are not uncommon particularly in regions where enteric fevers are endemic, it will be readily understood how essential it is to determine the prevalence and the exact nature of the organism or organisms concerned.

Here we would stress two points that have not received sufficient attention in many bacteriological laboratories in India. Firstly, the old-fashioned Widal reaction is full of many pitfalls and is of limited value. The qualitative-receptor-serological analysis of Weil and Felix particularly for the diagnosis of enteric fevers has received little attention in this country. There is no need to describe here the principles and technique of this comparatively new diagnostic method. These can be found in

any standard textbook and a vast literature is available on the subject. There can be no doubt that the claims advanced in favour of this method have been amply confirmed by many workers. There is no justification, whatsoever, in the retention of the old Widal reaction either in the sero-diagnosis of enteric fevers or in the determination of so-called normal agglutinins. Secondly the limit of agglutinins is directly dependent on the sensitiveness of the antigens employed and it is essential for the results to be comparable, and this indeed is the first desideratum in serological surveys, that some uniformity in the methods and antigens employed be obtained. There is a real need for a central co-ordinating committee which will lay down standard methods and guide workers in the planning and execution of serological surveys.

Summary

(1) The value of qualitative-receptor analysis of Weil and Felix for the determination of so-called normal agglutinins for the enteric group of organisms is stressed.

(2) A series of sera from 280 patients suffering from various non-enteric infections have been examined for 'O' and 'H' agglutinins for *Bact. typhosum*, *Bact. paratyphosum A* and *Bact. paratyphosum B*. The results obtained have been analysed and the available data suggest that the infection with these three principal organisms of the typhoid-paratyphoid group is common in Calcutta.

(3) The importance of serological surveys to map out the degree of infection in different parts of India and in different occupational and social strata is stressed.

(4) Suggestion is made that for such serological surveys to be of real value, some uniformity in the suspensions used and the methods employed in the different laboratories should be arrived at.

TUBERCULOSIS IN SOME RARE SITUATIONS, NAMELY TONSILS AND UTERUS

By K. G. KRISHNASWAMY, M.B., B.S.

AMAR NATH GOYLE, M.B., Ph.D.

and

A. VASUDEVAN, M.B., B.S.

(From the Department of Pathology, Medical College, Madras)

OUR choice of the title of this paper is not a very happy one, but may be justified on the ground that its splitting would reduce the papers to very small dimensions.

PART I

Incidence and Histopathology of Tonsillar Tuberculosis

Tuberculosis of the tonsils is by no means a common condition, Mullin (1923), for example, in analysing 400 tonsillectomies found only 4.25 per cent cases of tuberculous tonsils.

The present study is based on 2,477 tonsillectomies in the Madras General Hospital. This

series covers a period of five years from January 1928 to December 1932. We, however, feel that this investigation is incomplete in many respects; for example, there are no clinical details, and no bacteriological examination was made of the tonsils. It would undoubtedly have been more valuable if the incidence of the various types of *B. tuberculosis* had been worked out. But situated as we are, we could not carry out such enquiries. A very large number of persons come to the outpatient department and the patients leave the hospital soon after the operation. These tonsils are sent to the laboratory without any clinical history. We fully realize that information regarding the condition of the lymph nodes and the lungs would have been extremely useful inasmuch as it would have enabled us to establish the relationship between the incidence of tuberculous tonsils and tuberculosis of other parts of the body. As a very large number of tonsils are received for examination, no special investigations were carried out and only histological examinations were made. As will be seen in the table, only a very small proportion of the tonsils show histological evidence of tuberculosis. As this lesion is not recognizable clinically, it would have been necessary to submit thousands of the tonsils to bacteriological examination, such as animal inoculation and cultural tests. Such an investigation besides being very expensive would have entailed an enormous amount of labour.

Naked-eye examination

The tonsils were carefully examined before they were sectioned but in no case was it possible to identify the tonsil as tuberculous before it reached the microscope. The tonsils which turned out to be tuberculous on histological examination did not show any difference in size, colour, or appearance from the non-tuberculous ones. Fordyce and Carmichael (1914) have often found these tonsils to be small, ragged and atrophic. Though such an appearance was not noted in our series of cases, tonsillar tuberculosis being chronic in type and leading to fibrosis, one would naturally expect them to be small in size as the result of the contraction of fibrous tissue. It may be that in none of the cases of the present series had the fibrotic process advanced far enough to cause shrinkage. No case of ulceration was seen; even tonsils showing histologically an advanced degree of tuberculosis were free from it.

Histological examination

In the following paragraphs, the histological appearances of the tonsils in a few cases are described:—

Case I.—(Section No. 3910). The section shows a number of discrete typical tuberculous follicles under the squamous epithelium which is nowhere destroyed. These follicles which are situated in between the hyperplastic germinal centres consist of clusters of endothelial cells which are also known as epithelioid or

reticular cells and giant cells with a peripheral zone of small lymphocytes. There is no necrosis of the central zone and there is no increase of fibrous tissue.

Case II.—(Section No. 5040). The tuberculous follicles in this section are seen to have become confluent. Giant cells are also seen. Under the surface epithelium numerous hyperplastic germinal centres are noticed. The reticular cells and giant cells are situated deep down near the capsule which is thickened. There is marked infiltration of the tonsil with plasma cells. There is necrosis as shown by the loss of the cellular outlines of the reticular cells. There is no increase of fibrous tissue. This appears to represent a more advanced stage than the last section.

Case III.—(Section No. 4820). This section presents the appearance of formative or proliferative type of tuberculosis as seen in the lymph nodes. There are a number of cellular areas which stain differently from the rest of the tonsillar substance, i.e., they are eosinophilic. Under high magnification these cell groups are found to consist of reticular cells. There are no giant cells and the lymphocytic peripheral zone is also not very prominent. There is no necrotic change in the reticular cells. The germinal centres appear normal in size. There is a considerable increase of fibrous tissue.

Case IV.—(Section No. 5768). There are a few typical tuberculous follicles in contact with the surface epithelium, separated from one another, showing a slight amount of necrosis. There is an enormous increase of fibrous tissue in the tonsillar substance. Lymphoid tissue is atrophied.

Case V.—(Section No. 5316). The surface epithelium is much thinned out but not broken through. There is a diffuse hyperplasia of reticular cells without any definite follicular arrangement, amongst which a number of giant cells are seen. There is no evidence of fibrosis or caseation. The germ centres are atrophied.

Case VI.—(Section No. 4932). Numerous tuberculous follicles, some of which are confluent and others discrete. The germ centres are very active and no giant cells are seen.

Case VII.—(Section No. 3424). Numerous confluent areas of hyperplastic reticular cells; no necrosis or fibrosis.

Case VIII.—(Section No. 9042). Many tuberculous follicles; no necrosis or fibrosis.

Bacteriological examination

All the sections were stained by Ziehl-Neelsen's method and examined for *B. tuberculosis*, but in no case were these found.

Discussion

In 2,477 cases (males 1,249 and females 1,228) in which operation was performed for removal of the tonsils, histological evidence of tuberculosis was found in 15 cases, or 0.6 per cent of all cases. The percentage incidence of tuberculous tonsillitis in males was 0.4 and in females 0.8. According to age and sex, the incidence is as follows:—

Age	NUMBER OF CASES	
	Males	Females
1 to 5 years ..	nil	1
6 to 10 " ..	3	1
11 to 15 " ..	nil	nil
16 to 20 " ..	1	5
21 or over " ..	2	3

There were 10 females and 5 males, a proportion of 2 females to 1 male. The disease is

definitely much more frequent in females than in males after 15 years of age. This appears to be in accord with the observation made by many workers in India that pulmonary tuberculosis is more common among females than males. The maximum incidence is between the ages of 16 to 20. The youngest patient was 5 years of age and the oldest 26 years of age. Both were females.

It may be noticed that no case of tuberculous tonsillitis was found between the ages of 11 to 15 years but this is probably without any significance.

Histopathology.—The tuberculous process begins in the form of one or two discrete tubercles beneath the epithelium of surface and crypts. These gradually enlarge, become confluent, and extend into the substance of the tonsil until a great part of it is replaced by tuberculous tissue. It is a noteworthy fact that though the tubercles may lie near the epithelium they never actually invade it and it is for this reason that ulceration does not occur. It may also be noticed that caseation is not a very important feature of tonsillar tuberculosis. In only two cases was evidence of commencing necrosis found, but it was not at all marked. In most of the cases, proliferation of the reticular cells and fibroblasts was very pronounced. It is not possible to explain the remarkably different character of the tuberculous lesion of tonsils—different from that of the lymph nodes, for example, which undergo extensive caseation. It may be that the proliferative type and the fibrotic type of tuberculosis are met with in those tissues which are resistant to the destructive action of the bacilli and their toxins. Situated as the tonsils are in the common portal of entry to the respiratory and gastro-intestinal tract they are presumably infected with *B. tuberculosis* in a great many cases, but, as they withstand the action of the tubercle bacilli so well, they seldom present clinical evidence of the lesion. Histological evidence points to the fact that the ultimate tendency of the tuberculous lesions in the tonsils is towards recovery. In the routine examination of the tonsils, we have come across numerous instances in which widespread fibrosis was present and these might well represent an extinct tuberculous infection though, of course, there are no means of confirming this. Tuberculous infection may spread to the peritonsillar tissues causing peritonsillitis, which is clearly seen in our case II.

The material for this study came into our hands through the courtesy of Mr. P. V. Cherian, F.R.C.S.E., to whom our thanks are due.

PART II

Histopathology and Clinical Features of Tuberculosis of Uterus

Reports of cases

Case I. Clinical history.—Patient M, female, aged 25 years, was admitted into the Clough Memorial

Hospital, Ongole, with a complaint of prolapse of the uterus (duration two years) and serosanguineous discharge (duration six months). On examination there was ulceration of the cervix unlike that due to carcinoma. At operation, the peritoneal surface was covered with fine nodules but the absence of any primary tumour was against the diagnosis of carcinomatosis. The pouch of Douglas was obliterated by adhesions. The Fallopian tubes and ovaries were adherent to a mass of tissue. One of the tubes showed definite tubercles. The uterus along with the adnexa of both sides were removed.

Naked-eye examination.—On opening the uterus a soft raised ulcerated mass is found in the fundus and body of uterus without any extension to servix (Fig.). The uterus is normal in size and soft.

An irregularly raised mass is seen occupying the fundus of the uterus.

Microscopical examination.—(Section No. 2358). Under low power there is thickening of the endometrium. In one part of the section the uterine glands are absent and the endometrium is replaced by tuberculous granulation tissue. The surface epithelium is ulcerated. In other areas the glands appear normal without any hyperplastic changes. A few of the glands are distended and the lumen contains a hyaline secretion and a good number of large oval cells with a clear cytoplasm and peripheral nucleus. There are commencing areas of necrosis as seen by loss of cellular outline. There is no definite caseation. Giant cells of Langhans' type are present. There is marked infiltration of stroma with plasma cells and lymphocytes. There is neither stratification of glandular epithelium nor obliteration of the lumen. The myometrium shows definite tuberculous follicles between the muscle bundles but without caseation. The blood vessels show endarteritis obliterans.

Case II. Clinical history.—Patient D, female, aged 25 years, gained admission to the Clough Memorial Hospital, complaining of leucorrhœa and amenorrhœa of two years' duration. There was no disease of the lungs. A fluctuant fixed mass was felt in the right groin, believed to be a cold abscess resulting from the breaking down of tuberculous groin glands. An irregular ulcerated soft mass was protruding from cervix with no special tendency to bleeding. At operation, the tubes and ovaries presented the picture of advanced pelvic inflammatory disease. The adnexa of both sides were removed with the uterus, including the cervix and a small cuff of vagina. There was a profuse discharge from the cervical canal during operation. The patient died three days later with the evidence of general septic peritonitis.

Microscopical examination.—(Section No. 1542). Section of cervix shows ulceration of

surface epithelium, the cervical mucous membrane being almost entirely replaced by tuberculous granulation tissue with many giant cells. A few atrophic glands are seen. The muscular layer shows many tuberculous follicles and round cells. The blood vessels show definite endarteritis obliterans. Both ovaries are free from tuberculosis.

Case III. Clinical history.—Patient C, female, aged 23 years, married, has three children, the last child was born 2 years and 6 months before the date of admission to the hospital. She entered the Government Women and Children Hospital, Madras, on 25th January, 1935, complaining of pain on the right side of lower abdomen for four days, and fever of fifteen days' duration. For one year she has been having regular, painful and profuse periods, lasting for nine days. She has been suffering from leucorrhœa for the last two years. On examination, the cervix was found to be eroded, and the uterus slightly bigger than normal, and firm. There was tenderness in the region of the left Fallopian tube. The right ovary was palpable. It was diagnosed as a case of sub-involution and salpingitis. On 9th February

the uterus was dilated and curetted. On 21st February total hysterectomy was done and the tubes were found to be thickened and nodular. The ovaries were found to be covered with fine tubercles.

Naked-eye examination.—No gross lesion is found in the uterus or appendages.

Microscopical examination.—(Section No. 333). A section of the uterus shows the endometrium to be normal. There are typical tuberculous follicles situated in between the muscle bundles in close relation to blood vessels. There is no necrosis. A section of the ovary shows a large follicular cyst, but there is no evidence of tuberculosis. The wall of the Fallopian tube is slightly fibrotic and shows general thickening of the mucous membrane. The epithelium is intact. The serous surface shows a tuberculous nodule consisting of confluent tubercles. The central necrosis is well marked. The lumen of the tube is obliterated by the proliferation of the epithelium.

Case IV. Clinical history.—Patient K, female, aged 20 years, was admitted to the Government Women and Children Hospital, Madras, on 17th July, 1935. She was married seven years before the date of admission and one year later had a child. She complained of white discharge *per vaginam* since the birth of her child, and slight bleeding for one year. The periods were regular but very scanty, lasting only for one day, and she complained of slight pain in the back during the periods. On examination, there was a small ulcerated cauliflower-like growth on the right side of the cervix, which easily bled on manipulation. The growth extended to the anterior fornix of the vagina. On 29th July total hysterectomy and right salpingo-oophorectomy was done. A few nodules on the uterus, right Fallopian tube and on the intestines were noticed. The right ovary contained a hæmorrhagic cyst of the size of a lime.

Microscopical examination.—(Section Nos. 1735 and 1736). Section of the cervix showed typical tuberculous follicles situated in the stroma between the glandular acini. There is no evidence either of necrosis or of hyperplasia of the glandular epithelium. Section of growth from the anterior fornix showed tuberculous granulation tissue.

Case V. Clinical history.—Patient S, female, aged 25 years, had a child five years before the date of admission to St. Martin's Hospital, Ramnad. Her chief complaint was leucorrhœa and amenorrhœa of two years' duration. The cervix was eroded and bled readily when touched. The uterus was normal in size and position. The surgeon was inclined to think that the appearance of the cervix was not that of a typical erosion and he removed a wedge-shaped slice of the cervix bearing the erosion.

Microscopical examination.—(Section No. 7575). Section of the cervix shows ulceration of surface epithelium. Many confluent tuberculous follicles are seen in the fibro-muscular tissue with a large number of giant cells. There is no necrosis or caseation. There is no evidence of proliferative activity of the glandular epithelium.

Case VI. Clinical history.—Patient M, aged 26 years, was admitted into the Government Women and Children Hospital, Madras, on 22nd August, 1934, with

a complaint of complete amenorrhœa of four years' duration. She was married five years, had no children. The periods used to be regular till four years before admission to the hospital. The general condition of the patient was fair and nothing abnormal was noticed in the circulatory or respiratory system. On local examination, there was an ulcer on the cervix.

Microscopical examination.—(Section No. 1705). Section of cervix shows an ulcer subjacent to which is seen tuberculous granulation tissue with areas of necrosis. The glandular acini are almost completely atrophied. The small blood vessels of the muscular layer show perivascular round-cell infiltration.

Case VII. Clinical history.—Patient S, female, aged 32 years, sought admission into the Government Women and Children Hospital, Madras, on 2nd December, 1935, with a complaint of irregular bleeding *per vaginam* alternating with leucorrhœa for a period of five months. She was married eighteen years before admission to the hospital and had five children, the last child being six years of age. She was very anæmic and poorly nourished. She gave a history of a swelling in the neck six years ago which burst leaving a visible scar at the site of the swelling (caseating tuberculous glands?). On physical examination of the chest a few râles were heard in the right apex. There was no definite dullness. A skiagram of the chest revealed nothing abnormal in lungs. Local examination of the cervix revealed an irregular hard ulcer of both lips extending into the right lateral fornix. The margins of the ulcer in some places were sharply defined and were not specially friable. The uterus was enlarged and retroverted. On rectal examination, a certain amount of infiltration was felt in both broad ligaments.

Microscopical examination.—(Section No. 2815). Section of the cervix shows ulceration of the mucous membrane at one part with subjacent fibro-myomatous tissue. Scattered here and there are seen typical tuberculous follicles with very little necrosis. Most of these are seen at considerable depth in the tissue. Groups of round cells and plasma cells are seen throughout the section.

Case VIII. Clinical history.—Patient A, female, aged 20 years, was admitted in the Government Women and Children Hospital, Madras, on 26th November, 1935, with a complaint of leucorrhœa and scanty but prolonged periods for two years, the periods lasting for about fifteen days. She was also suffering from attacks of pain in the right iliac fossa with vomiting. Her general condition was fair though anæmic. Physical examination of heart and lungs revealed nothing abnormal. On local examination, the cervix was found to be hard and hypertrophied with a number of nodules on it. The uterus was retroverted, bigger than normal, freely movable and tender. The right ovary was prolapsed.

Microscopical examination.—(Section No. 2716). Section of the cervix shows at one part a lining of columnar epithelium with subjacent dense fibrous tissue and involuntary muscle tissue. Numerous hyperplastic tuberculous follicles are seen densely packed in the sub-epithelial tissues. There is marked proliferation of endothelioid cells with complete absence of necrosis.

Discussion

Tuberculosis of the uterus is a rare affection. It is most common in adults, the average age

incidence in our collection of cases being 28 years. The age, symptoms, etc., of the cases are shown below :—

duced into the peritoneal cavity found their way into the uterus and vagina through the Fallopian tubes. The possibility of the spread

Serial number	Age	Symptoms and duration	Pre-operative diagnosis	Evidence of tuberculosis apart from uterus
1	55	Serosanguineous discharge (6 months).	Tubercle or cancer	Peritoneum and fallopian tube.
2	25	Leucorrhœa and amenorrhœa (2 years).	Tubercle	Groin glands.
3	23	Profuse painful periods (1 year).	Chronic endometritis	Fallopian tube.
4	20	Bleeding (1 year), leucorrhœa (6 years).	Malignant	Intestines and fallopian tube.
5	25	Leucorrhœa and amenorrhœa (2 years).	Do.	<i>Nil.</i>
6	26	Leucorrhœa and amenorrhœa (5 years).	Do.	<i>Nil.</i>
7	32	Bleeding and leucorrhœa (5 months).	Malignant and tubercle	Glands neck.
8	20	Scanty but prolonged periods (2 years).	Malignant	<i>Nil.</i>

Clinically the most common symptom is leucorrhœa even though some of the patients complained of amenorrhœa and others of bleeding *per vaginam*. The duration of the symptoms varied from a period of five months to six years. There was histological evidence of tuberculous cervicitis in all cases except one (case I). Cases III, V and VI showed an ulcerative condition of the cervix which simulated cervical erosion. In two cases (II and IV) there was an ulcerated cauliflower-like growth in the cervix which very much resembled a malignant growth. As a matter of fact the pre-operative diagnosis in most cases was that of malignant disease. This shows that histological examination of the affected tissue is of particular importance in the correct diagnosis of uterine tuberculosis, since there are no definite clinical signs or symptoms pathognomonic of this disease. Evidence of abdominal tuberculosis was present in cases I and IV, whereas in case III, apart from tubercles on Fallopian tubes, no other focus was discovered. In case II there was a cold abscess in the right groin even though there was no disease of the respiratory system. There was a history of old glandular tuberculosis in case VII. In cases V, VI and VIII there is no evidence of any other focus of tuberculosis apart from cervix and the possibility of primary tuberculosis of this tissue is to be considered. The mode of infection in cases of primary tuberculosis is uncertain and on account of lack of clinical data we are not able to trace the infection in these cases to infection by coitus from genito-urinary tuberculosis. The uterine infection in case I is obviously secondary to peritoneal infection. The infection might have spread from the peritoneum to the uterine mucosa *via* the Fallopian tubes as suggested by the experiments of Pinner, who showed that

fine particles of cinnabar or lamp black introduced through the entire thickness of the uterine wall is remote. Case III is an example of miliary type of tuberculosis. The endometrium is not affected at all and the myometrium shows miliary tubercles in close relation to blood vessels, suggesting a hæmatogenous spread.

Histologically, in early cases the tubercle follicles are situated beneath the surface epithelium in the stroma between the glandular acini. These gradually coalesce, undergo caseation and cause ulceration of the surface epithelium. A rare interstitial type has been described in which there is a diffuse enlargement of cervix with intact surface epithelium (Frank). Case VIII illustrates such a type. It has been noted by some authors, particularly by von Franque, that in tuberculosis of the cervical mucosa there is stratification of glandular epithelium and obliteration of the lumen of the acini. This has not been observed in our cases.

Summary

The first part of this paper is based on a study of fifteen cases of tuberculous tonsils met with in a series of 2,477 tonsillectomies. The incidence and histopathology are discussed.

The second part is devoted to the study of eight cases of tuberculosis of the uterus. The clinical features and histopathology of these cases are described as fully as possible.

NOTES ON PNEUMONIA IN A TEA GARDEN IN ASSAM

By RASAMAY BHATTACHARYYA, L.M.P. (Assam),
D.T.M. (Cal.)*Bokpara Tea Estate, Doom Dooma, Assam*

DURING a period of 5 years from January 1930 to December 1934, 242 cases of pneumonia were treated in this hospital. Of these, 7 were of larval type with indefinite lung signs. Two other cases manifested all the characteristic features of lobar pneumonia, except that no lung signs could be elicited. They were diagnosed as central pneumonia and both of them died. No post-mortem examination could be held to confirm the diagnosis. These 9 cases have been excluded and the remaining series of 233 cases which had definite lung signs have been analysed and the observations briefly recorded in the following pages.

It is not the object of this paper to give a full description of the disease but only the points of interest that have emerged and the experience that has been gained in dealing with these cases have been communicated. The population from which the patients have been drawn and the houses they lived in as well as their economic condition were such as are found in an average tea garden of Assam. With the advent of the cold season the manager of this garden advances warm blankets and coats to the big and needy families as a precautionary measure against pneumonia.

Classification.—It has appeared to me that a strict clinical distinction between lobar and broncho-pneumonia is not always possible. Moreover atypical cases are far more common than the classical lobar and broncho-pneumonias of the textbooks. These atypical cases are usually ushered in with fever, cough, bad headache, pain in the whole body or joints and running from eyes and nose. The temperature generally continues for 2 or 3 days, then drops to normal and remains there for one or two days when the patient feels better, though somewhat exhausted. Then there is a sharp rise of temperature again with pain in the chest, return of headache and aggravation of cough which is often hacking and persistent in character. The sputum is often purulent, sometimes frothy, yellow or greenish yellow. Either one or both the lungs now show crepitations, most commonly at the base or bases, which extend upwards and run to consolidation. The temperature continues, though irregularly, and ultimately comes down to normal, usually by lysis and rarely by crisis. This type of case is demonstrated in chart 'A'. There is another group in which the onset is the same but there is no intervening drop of temperature. The chart is more irregular and the lung signs appear in a day or two. This is demonstrated in chart 'B'. There is yet another group, though a small one, in which patients are admitted with vomiting and purging,

sometimes in a semi-collapsed condition with a subnormal temperature and a feeble pulse. They are primarily diagnosed as acute enteritis and some of them require subcutaneous saline. In

CHART A

two or three days' time they get fever, cough and chest pain, and develop pneumonia of one or both lungs, and run an irregular temperature ending by lysis. When all the clinical pictures present

CHART B

in these cases are weighed-up, it becomes very difficult for the attending physician to place them in any of the categories of the classical pneumonias.

Some might like to call them mixed-infection pneumonias but I prefer to classify them as influenzal pneumonia, based on the modes of onset, the type of pyrexia, the character of symptoms and physical signs, the duration of the disease and the mode of defervescence. According to the best of my judgment, these cases of influenzal pneumonia markedly outnumber those of typical lobar and broncho-pneumonia.

OBSERVATIONS

Incidence of various types.—Table I shows the relative incidence of the three types of

TABLE I
Showing types of cases

Types	Number of cases	Percentage
Lobar	68	29.1
Broncho	29	12.4
Influenzal	136	58.3
TOTAL	233	..

pneumonia treated in this hospital. It is evident that the influenzal types are much higher than the other two types separately and even taken together. Broncho-pneumonia mostly affected children below 5 years of age but adults were not exempt. Both in broncho- and influenzal pneumonia there was not much alteration of pulse-respiration ratio. Even in a few cases of lobar pneumonia with definite consolidation pulse-respiration ratio was hardly altered, which denoted low toxicity and terminated in rapid

of life, both in males and females, leading to exertion, excesses and exposure to infection.

Incidence by months.—Table III shows the monthly incidence of the disease. It is noted that no month is exempt and that the cases are highest in number in May and August. At the end of April the coolies enjoy 'Fagua' holidays. The large number of cases in May is the outcome, it seems, of exposure along with alcoholic and other excesses committed during 'Fagua'. In August there is heavy rainfall and the people

December ..	2	2	5	..	2	11	4.7
GRAND TOTAL ..	30	28	61	47	67	233	..

recovery. Apical pneumonia was very rare, only 4 such cases being found in the whole series, 3 of them being children and 1 an adult. It must also be noted that toxicity does not necessarily depend on the extent of lesion. I have seen cases with insignificant lesions having highly toxæmic symptoms and cases with extensive lesions showing little or no toxæmia.

Age and sex incidence.—Table II shows the incidence by age and sex. It is manifest from this table that males are more affected than females. This is due, I think, to the more strenuous and exposed life the males are bound to live and to their greater indulgence in alcohol. It is also noticed that the number of cases are highest between 10 to 50 years of age. This is natural because this is the most active period

are compelled to work outdoors, wet all over throughout the day. This, I think, leads to the heavy pneumonic incidence in August.

Lung involvement.—Table IV shows the relative involvement of the lungs. It is noted that the right lung is most affected.

TABLE IV
Showing lung involvement

Lungs involved	Number of cases	Percentage
Right lung ..	101	43.3
Left lung ..	70	30.0
Both lungs ..	62	26.6
TOTAL ..	233	..

Duration of pyrexia.—Table V shows the duration of temperature in days. Broncho-pneumonia had the longest duration and lobar the shortest. In taking this average, the patients who died during pyrexia or false crisis have been excluded. The average has been taken of those cases only who had real crisis or lysis.

TABLE V
Showing duration of temperature in days

		Maximum	Minimum
Lobar ..	6.2	16	3
Broncho ..	12.6	37	10
Influenzal ..	7.2	20	3
TOTAL AVERAGE ..	8.6	24.3	5.3

MORTALITY

Mortality by age and sex.—Table VI shows mortality by age and sex. It is found that the death rate is higher in females than in males, and that taking both sexes together it is highest in extremes of life. It is also noted that in age group 5 to 10 years the death rate is nil. This is in conformity with the observations of Leslie (1924) who mentions a very low death rate in this age period.

TABLE VI
Showing mortality by age and sex

		AGE GROUPS									TOTAL	Per cent
		Below 1 year	1-5	5-10	10-20	20-30	30-40	40-50	50-60	60 and over		
Total deaths in each age group.	Male ..	5	4	nil	3	7	11	8	2	nil	40	25.8
	Female ..	1	2	nil	6	5	7	nil	nil	1	22	28.2
Percentage of deaths in each age group.	Male ..	45.4	30.7	nil	18.7	20.5	28.9	28.5	28.5	nil
	Female ..	33.4	11.1	nil	40.0	35.7	43.7	nil	nil	100.0

Mortality and types of pneumonia.—Table VII shows mortality according to types of

TABLE VII
Showing types and mortality

Types	Number of cases	Number of deaths	Percentage
Lobar ..	68	26	38.2
Broncho ..	29	10	34.4
Influenzal ..	136	26	19.1
TOTAL ..	233	62	26.6

pneumonia. The lobar type shows the highest mortality and the influenzal the least. This is contrary to the opinion of Leslie who states that the death rate in influenzal pneumonia is higher than that in the other two types.

Mortality and lobar involvement.—Table VIII shows the mortality according to lobar involvement. It is obvious from this table that the greater the number of lobes affected, the higher the death rate.

TABLE VIII
Showing mortality and lobar involvement

Number of lobes involved	Number of cases	Number of deaths	Percentage
One lobe ..	73	13	17.8
Two lobes ..	84	23	27.3
Three lobes ..	40	13	32.5
Over three lobes	36	13	36.1
TOTAL ..	233	62	26.6

Mortality and day of admission to hospital.—Table IX shows the mortality according to the day of admission of the patients to hospital. This table clearly demonstrates the necessity of admitting patients early. But one thing must be remembered. They should never be allowed to walk to the hospital. In this garden it is

the custom to bring the patients to hospital either on a trolley or in a lorry slowly driven, from which they are carried to bed on a stretcher.

PROGNOSIS

It is my deep-rooted impression that it is not wise for a physician to predict a prognosis as to recovery or death in acute cases of pneumonia. I have seen very bad cases recover when all hopes of cure had been given up and again apparently good cases die when death was never expected. But some general points can be laid down. In one word, the degree of toxæmia gives the most important indication for prognosis. The favourable signs are (1) ability to

TABLE IX
Showing mortality and day of admission to hospital

	DAY OF DISEASE ON ADMISSION								TOTAL
	1	2	3	4	5	6	7 and over	Not definitely known	
Number of cases admitted.	138	26	37	19	8	3	1	1	233
Number of deaths ..	29	7	13	6	4	1	1	1	62
Percentage	21.0	26.1	35.1	31.5	50.0	33.3	100.0	100.0	26.6

take nourishment, (2) moist tongue, (3) bright and comfortable appearance, (4) loud cough with free expectoration of sputum, (5) temperature below 104°F., (6) pulse rate 110 to 120, (7) respiration rate below 40, (8) sufficient urination, (9) absence of nervous symptoms, and (10) good sleep. Unfavourable signs are (1) anxious and distressed appearance, (2) early cyanosis, (3) temperature above 104°F., (4) pulse rate above 120, (5) respiration rate above 40, (6) continued digestive disturbance specially tympanitis, (7) scanty urine, (8) low husky ineffective cough with scanty expectoration, (9) insomnia, (10) delirium, (11) lowering of temperature without reduction in pulse and respiration rate, and (12) typhoid stupor.

COMPLICATIONS

Complications were rare in this series. The few that were met with are noted below:—

Post-pneumonic œdema (mostly limited to lower extremities only)	27
Effusion (non-suppurative) ..	1
Arthritis (suppurative) ..	1
Do. (non-suppurative) ..	1
Otitis media ..	1
Parotid abscess ..	2
Corneal ulcer ..	1
Bacillary dysentery ..	2

Sequelæ.—All the cases of the series could not be followed as some of them left the garden later on. Among those who remained in the garden one case developed tuberculosis to which he succumbed.

Immunity.—In the present series 8 cases had recurrent attacks of pneumonia and 3 of them died in later attacks. This shows that immunity acquired in pneumonia is only temporary.

TREATMENT

It is not my object to describe the treatment of my cases in detail. The broad outlines of treatment are as follows:—

(1) After diagnosis has been established, minimal examinations are done.

(2) Antiphlogistine is applied hot in the first stage, only on the back and sides but not in front.

(3) A piece of warm flannel is loosely wrapped round the chest without causing hindrance to free respiration.

(4) When there is no draught, patients are kept in the hospital verandah, in complete rest in special pneumonia beds, under warm and light blankets.

(5) Strong purgatives are avoided. If the bowels are not properly moved, liquid paraffin is given at night. An enema is only rarely given as it is not much favoured by coolie patients.

(6) Sufficient fluid drinks are allowed. Bottles containing glucose solution in normal saline, as well as bottles of soda-water, are kept by the bed-side to enable the patient to drink as often as he likes.

(7) Milk, sago, tea and essence of chicken form the major items of diet.

(8) Digitalin, strychnine, adrenalin and camphor in oil are the cardiac stimulants usually used.

(9) For hacking cough codein phosphas is prescribed, especially at night.

(10) Good sleep is ensured. Chloral hydras and bromide, ortal and brandy are the remedies generally used as hypnotics. Morphine is rarely used and only with great caution.

(11) Oxygen inhalation is given when the respiration rate is 40 or upwards.

(12) Tepid sponging is done when the temperature is 104°F. or higher.

(13) Digestive disturbances and nervous manifestations are carefully watched and treated accordingly.

(14) The time-honoured potassium iodide and creosote mixture is given for the first 3 or 4 days, and, as soon as the sputum is loose, patients are placed on a simple stimulant mixture in lobar pneumonia cases and on stimulant expectorant mixture in broncho- and influenzal ones.

(15) During convalescence some preparation of cod-liver oil is given, usually Kepler's malt extract with cod-liver oil.

In this connection it is worth while to touch briefly on a few confusing points of treatment :

(1) *Local treatment*.—Local treatment is of value when judiciously administered. Nowadays use of antiphlogistine or any allied preparation has become a fashion. A private practitioner, who does not advise it, falls into disrepute. But unfortunately on many occasions it does more harm than good by impeding the free movement of the chest from its injudicious application. The chief indications for local treatment are pain and tightness in the chest. The value of antiphlogistine lies in its counter-irritant effect. Therefore, if it is to be applied, it should be applied in the first stage of the disease, only on the back and sides and never in front, as it impedes the movement of the chest and the heat of the application embarrasses the heart of an already febrile patient. The same result can be obtained by rubbing simple things like oil of turpentine or liniment ammonia and then lightly wrapping the part in a piece of warm flannel.

(2) *Alcohol*.—There is much divergence of opinion as to whether it should be used or not. Osler and McCrae (1921), Leslie (1924), Savill (1925) and Joules (1933) advocate it whereas Woodford (1933) deprecates its use except in alcoholics and the aged. My personal experience is that it is not necessary to give it as a routine measure, but it should be given when there is marked toxæmia, insomnia and delirium.

(3) *Morphine*.—It is found in textbooks that morphine is a valuable drug to relieve pain and induce sleep in pneumonia. I have learnt by bitter experience that great caution and judgment should be used as to when and to whom it should be given. It should never be administered in conditions of toxæmia and cyanosis, nor to children.

(4) *Quinine*.—Many physicians speak highly of the value of quinine in reducing pyrexia and helping the recovery. I, however, am not so impressed. But I think three intramuscular injections of quinine should be given if the blood shows malaria parasites. Thirteen cases in the present series showed scanty malaria parasites in peripheral blood, 6 being benign tertian and 7 malignant tertian infections. They were treated by quinine with good result. Authorities are almost unanimous that two acute diseases cannot run together. Finding of malaria parasites here means that pneumonia had developed in malarial subjects.

(5) *Cardiac stimulants*.—Here also opinions are divergent. Some authorities advocate its use from the very beginning while others reserve it for administration in later stages. I think, in young and healthy adults with little or no toxæmia it should be withheld till the symptoms of cardiac debility just manifest themselves, whereas in the aged, the debilitated and the highly toxæmic cases, it should be exhibited from the very beginning.

(6) *Oxygen therapy*.—Some authorities advise oxygen inhalation as soon as a diagnosis had been made, but the majority agree that it is indicated only when there is definite cyanosis or anoxæmia. When administered, it should be passed through warm water. McCurdy (1933) advises continuous administration of oxygen day and night by nasal catheter, the guiding principle being 'keep the finger nails pink'. He considers the administration by means of a funnel absolutely useless. In this hospital oxygen inhalation is given when the respiration rate is 40 or higher, but unfortunately by a funnel which is held over the patient's mouth and nose. In fact, I have hardly ever heard a patient bless me for this procedure.

(7) *S. U. P. 36 and iodine*.—Often we hear doctors claiming 'marvellous results' in pneumonia cases some with intramuscular injections of S. U. P. 36 and others with intravenous iodine. In 1932 I was asked by my former chief, Dr. D. P. Williams, to ascertain how far those claims were correct. Accordingly an experiment was taken up in which, in rotation, one was treated with iodine, a second with S. U. P. 36, the third one being treated on the usual lines as a control. No selection was made in the choice of patients of each group. Seventy-two cases were thus treated and the mortality rate is shown below :—

	Number of cases	Number of deaths	Percentage
Iodine ..	24	6	25.0
S. U. P. 36 ..	24	7	29.1
Controls ..	24	7	29.1

It is noticed that iodine therapy gave a little better result though not in any way 'marvellous'.

(8) *Steam inhalation*.—There are advocates of steam inhalation in broncho-pneumonia but much confusion exists as to when to use it. Personally I do not think there is much utility in this therapy but, if it is to be used, it should be used only in the early stage when there is scanty secretion but never when there is abundant secretion and cyanosis.

(9) *Serum and vaccine therapy*.—I have no personal experience of their use and value. But it is interesting to mention that Dr. Napier carried out research in the Jorhat district of Assam and found that pneumococcal types I and II were rare in that district, but isolated two other virulent local strains. He therefore concluded 'that the ordinary commercial serum which only acts in type I or type II will be of very little value in Assam, and that neither prophylactic vaccines nor sera will be of much use unless these two local strains are used in their preparation' (Napier and Dharmendra, 1935).

PNEUMONIA IN CHILDREN

The clinical picture of pneumonia in children diverges from that in adults in many respects. A quotation from Leslie is very impressive. He says 'as regards the clinical pictures, it is the atypical character of the symptoms and course of the disease which is the outstanding feature; and it is the aberrancy of type which adds so greatly to the difficulty of diagnosis, particularly in young children'.

The following are some characteristic features of children's pneumonia:—(1) High respiration rate, generally 50 to 80, (2) high pulse rate, generally 150 to 170, (3) no marked dullness, (4) diminished breath sounds or sometimes broncho-vesicular breathing, (5) absence of sputum which is usually swallowed, (6) remittent and relapsing character of pyrexia, (7) frequency of cerebral or gastro-intestinal symptoms, (8) greater tendency for complications, and (9) frequent absence of characteristic signs.

It must be noted that the child who appears irritable during illness generally progresses towards recovery and one who lies prostrated in bed usually declines towards a fatal end.

Principles of treatment are the same as in adults except that a child's position should be frequently changed in order to promote coughing and emptying of the bronchial tubes. Leslie advises occasional lifting of the infant out of bed and carrying it about in one's arms in order to bring on paroxysms of coughing which are apt to clear out the plugged bronchi. Emetics are useful in early stage when cough is feeble and there is accumulation of secretion. Opiates should not be used. Ammonium bromide with aromatic spirits of ammonia proves a valuable night sedative for a child. Hydrotherapy, specially a mustard bath, is of great service. Leslie recommends a combination of ammonium carbonate and ipecacuanha, but authorities are not unanimous on the use of expectorants.

SUMMARY

1. Two hundred and thirty-three cases of pneumonia in a tea garden of the Doom Dooma district have been reviewed.

2. Cases of influenzal pneumonia markedly outnumbered those of lobar and broncho-pneumonia.

3. Atypical clinical pictures were more common than the classical pictures of textbooks.

4. The largest number of cases were found between 10 to 50 years of age, but no age was exempt.

5. Males were found to be more affected than females; but the death rate was lower in the former. The gross mortality rate was 26.6 per cent.

6. The months of May and August showed the highest incidence, the reasons of which have been explained.

A CASE OF RHINO-MENINGORRHEA

By N. GUPTA, M.B., M.R.C.P. (Edin.)

Research Ward, Mifflord Hospital, Dacca

Discussion.—The central nervous system preserves its character as a hollow organ throughout life, beginning its development as a neural tube with a wide cavity throughout its length. The ventricle of the spinal cord does not seem to perform any important function.

The ventricular cavities in the normal adult brain form a continuous channel for flow of cerebro-spinal fluid throughout its length. If any part of this channel is occluded to prevent free circulation of its fluid, increased intra-cerebral pressure results in hydrocephalus or other serious pathological processes.

Dandy (1919) has actually produced experimental hydrocephalus by plugging the foramen of Monro in a dog.

Choroid plexuses are developed in the ventricles and most of the ventricular fluid is derived from the blood vessels of these plexuses by a process of filtration, osmosis and selective secretion.

The subdural space is scarcely more than a potential space. It contains a minimal amount of fluid. The subarachnoid space is traversed by connective tissue trabeculae. It contains a large amount of fluid and is independent of the subdural space.

(Continued from previous column)

7. No specific therapy was given. General outlines of treatment followed in this hospital have been described.

8. A few controversial and confusing points in treatment have been briefly dealt with.

9. The distinctive features of children's pneumonia have been briefly narrated.

10. The necessity of early admission of patients to hospital has been shown.

ACKNOWLEDGMENTS

I am indebted to my chief Dr. W. F. Whaley, M.D., for his kind permission to use the hospital statistics and for his valuable help in the preparation of this paper. My sincere thanks are also due to Mr. H. O. Swannell, the manager of the garden, for his unfailing co-operation and support in the management of the hospital.

The subarachnoid space is widened in a few places to form cisterns where the arachnoid is widely separated from the pia. The most important of the cisterns is cisterna magna. The fourth ventricle communicates with this cistern through three openings in its roof—a median foramen of Magendie and two lateral foramina of Luschka.

The cerebro-spinal fluid is the water-bed in which the central nervous system is suspended. This fluid protects the brain from mechanical injuries. Nutrient media and waste products are probably dissolved in it.

The subarachnoid spaces are in free communication and cerebro-spinal fluid may pass through them from end to end of the nervous system. The amount of the fluid is variable, estimated as 80 to 100 c.cm. or even as much as 150 c.cm. It differs in chemical composition from all other fluids of the body. It is limpid, slightly viscous and has a low specific gravity 1004 to 1008. It contains only traces of proteins, small quantities of inorganic salt, and dextrose and a very few lymphocytes (10 in 1 c.mm.).

The cerebral fluid is constantly renewed. It circulates slowly through the brain ventricles and through the meshes of the subarachnoid spaces. If these spaces are opened to the outside by injury in man, a large amount of fluid steadily drains off—200 c.cm. or more in a day.

The sources of this fluid.—Primarily the blood vessels of the choroid plexuses, pia mater and brain substances give origin to this fluid. From the brain substances the flow is outward into the subarachnoid spaces and from the choroid plexuses it flows inward into the ventricles.

More recent experimental studies indicate that the plexuses are wholly secretory and not resorptive in function. Absorption of fluid from the ventricles into neighbouring veins has been shown experimentally to take place through the ventricular walls [Wislocki (Cowdry, 1928)]. The chief source of ventricular fluid is the choroid plexuses, as has been shown by embryological studies of Weed (1914) and his colleagues.

Pettit and Girard (1902) showed that the flow of cerebro-spinal fluid is increased by drugs that stimulate secretion (pilocarpine, muscarine, etc.), and choroidal cell changes indicative of the activity.

The chief channel of discharge of ventricular fluid normally is from the lateral ventricles of the cerebral hemisphere where the fluid is derived from the lateral choroid plexuses, through the foramen of Monro into the third ventricle.

Here the fluid is added from the choroid plexuses. From the fourth ventricle it passes into the cerebello-medullary cistern, and from here it diffuses in all directions through the subarachnoid spaces. The pathway by which cerebro-spinal fluid passes from the subarachnoid

spaces back into the blood stream is very difficult. Some of it gets into extracranial lymphatics by way of perineural spaces within the sheaths of the cranial nerve roots.

The perineural spaces in the optic nerve are in free communication with the subarachnoid spaces. The arachnoid membrane is imperforate around nerve roots and any fluid that passes outward into perineural spaces must pass through it by extravasation.

A very small part of the cerebro-spinal fluid enters lymphatics or veins but most of it passes directly into the big endocranial venous sinuses through the arachnoid villi. By numerous well-controlled experiments it has been shown that the arachnoid villi provide the main pathway for outflow of cerebro-spinal fluid directly into the venous circulation (*vide figure*).

Diagram of coronal section of meninges and cerebral cortex to show relation of arachnoid villus to dural venous sinus. (After Weed.)

The case.—A male, aged 7 years 2 months.

History of previous illness.—At the age of (i) 2 months was attacked with pneumonia, at (ii) 7 months, again attacked with pneumonia and later on suffered from cough and fever occasionally, at (iii) 4 years 6 months, fever for 25 days treated as malaria, and at (iv) 5 years 2 months had a fall from a height of about 36 feet from a roof and remained unconscious for 5 days.

As a result of the fall he had the following manifestations:—(a) lacerated injury at the root of the nose, (b) bleeding from the right nares for about 2 weeks, (c) dribbling of watery discharge from the nares; since the bleeding stopped (the discharge is still persisting),

(d) a big swelling at the centre of the forehead which suppurated and eventually burst with discharge of pus (a scar mark is left), (e) an oblong swelling on the vertex, soft and compressible which disappeared with the bursting of the abscess on the forehead, and (f) swelling of the left eyelid which hung down to close the eye completely for about $1\frac{1}{2}$ months, and a dark red spot left on the eyeball when the swelling disappeared.

History of present illness.—(a) Irregular fever for two years. The fever often comes with chill and rigor, occasionally remains continuous for 7 or 10 days, and at times lasts for a day or so and comes down with sweating.

(b) Repeated dribbling of the watery discharge from the right nares which rarely dries up and reappears again.

He has been treated with quinine, atabrin, quino-hæmogen and other antipyretics with practically no effect, for the last two years.

X-rays.—No fracture or abnormality detected by the radiologist when the patient came for the examination of nasal discharge on 10th December, 1935.

Clinical findings.—The boy is fairly intelligent, takes interest in outside things, answers questions accurately, and does not delay in replying.

The upper surface of the lip is ulcerated and moist with fluid dribbling from the right nostril. About 12 c.cm. of discharge is collected in a test tube within 3 hours. The mucous membrane of the right nostril is thickened and ulcerated; left dry and healthy.

Laboratory findings.—(i) Examination of the nasal discharge (six samples were examined).

(a) *Naked-eye examination.*—Faintly turbid fluid with traces of mucus shreds floating in it.

Slight deposit at the bottom on standing.

It has not the yellowish-brown colour seen in old hæmorrhage into the subarachnoid space.

(b) *Chemical examination.*—Specific gravity—1004 to 1008; reaction—neutral; sugar content—variable percentage, in different samples, from 0.05 to 0.2 per cent or more; albumin content—variable in different samples, 0.01 to 0.05 per cent or so; globulin—no reaction; urea—10 mg. per 100 c.cm. or 0.01 per cent (only one sample tested).

(c) *Microscopical examination.*—Mucus shreds, nasal epithelial cells and a few lymphocytes are seen. No red corpuscles were detected.

Culture yielded pneumococci predominantly besides other mixed organism, e.g., *micrococci catarrhalis* and staphylococci.

The variability of the sugar contents in different samples remained unexplained. About 6 samples of fluid were examined on different occasions (estimation of sugar by Folin's method in a Klett colorimeter).

(ii) Glucose content in blood—0.08 per cent.

(iii) Examination of urine and blood—no abnormality detected.

Clinical diagnosis.—Coryza is a watery discharge associated with the watering of eyes. It is generally acute in onset, and the diagnosis of its cause is not difficult as a rule.

Common cold, lachrymation, iodism, bromism, arsenism and trigeminal neuralgia also cause excessive discharge from the nares.

Rhinorrhœa may be a result of neurosis.

The only other form of watery discharge from the nares is the escape of cerebro-spinal fluid, and the laboratory diagnosis showed the discharge to be such.

Conclusion.—There was a history of injury; the only possibility would be a fracture of the base of the skull involving the anterior fossa at the cribriform plate of the ethmoid with the rupture of the dura and arachnoid leading to the escape of cerebro-spinal fluid through this route. Extravasation of fluid through the perineural spaces in the optic nerve through the subarachnoid spaces is a less likely occurrence and the patient does not show any ocular disturbances.

The escape of fluid from one of the nostrils is a marked feature. The continuous flow of cerebro-spinal fluid for such a long time is interesting because dural defects are quickly repaired by formation of new dura.

It is difficult to explain the conditions under which the usual repair was not possible. Moreover, such a loss of fluid has not lessened the intracranial pressure, possibly the fluid lost has been replaced by increased secretion from the choroid.

The fluid discharge was continued for the last 2 years without any ill effects on the patient. No method is known to stop the cerebro-spinal fluid discharge. The advisability of stopping the flow of cerebro-spinal fluid is questioned as the choroid is secretory in function and will continue to secrete more and more, and serious pathological manifestations may be evolved by this procedure.

Occasional fever troubles him and it seems that it is due to local infection of pneumococci affecting the nasal cavities and the pharynx. Pneumococci are commensal in those regions and when they find a good nutrient medium in the constant presence of cerebro-spinal fluid discharge in the nasal cavities, they may occasionally become pathogenic and cause infection.

Extension of local infection into the meninges may lead to a fatal issue. It is, however, likely that nature has elaborated sufficient immunity against the infection to resist further extension into the meninges.

It is desirable that an autogenous vaccine should be tried to increase immunity against the local infection and it is expected that the fever may then be stopped.

The case is recorded on account of the comparative rarity of the condition.

MORE ON HILL MALARIA

By C. STRICKLAND, M.A., M.D., B.Chir. (Cantab.)
Professor of Medical Entomology
and

H. P. CHAUDHURI, M.B., D.P.H., D.T.M. & H., F.R.S.S.
Acting Assistant Professor of Medical Entomology,
School of Tropical Medicine, Calcutta

It has recently (1935) been suggested by the senior writer that the spring epidemic of malaria in the lower Himalayan hills was spontaneous, and different from that at Calcutta where it was only due to relapses, because of the local differences in the physical conditions, of which the temperature was the most important factor.

Another possible explanation, however, not then taken into consideration, was that human infection in the hills was acquired during autumn just as in Calcutta but did not appear till spring, as has been reported to happen in Holland.

With this possibility in view anophelines infected in Calcutta during the recent autumnal infective season were transported by us to the lower Himalayan hills and the behaviour of the Plasmodia watched. *A. stephensi* was used as one now knows that its infective rate in Calcutta is at this season very considerable and would afford a good datum line for the observations in the hills.

The result of these have been that while the anopheline was becoming infected in Calcutta, when used as a strict control, at a rate of 58.5 per cent*, in the hills the rate was about 6 per cent. Further the evidence adduced below will show that under more 'natural' conditions than obtained during our observations autumn infection in the mosquito in the hills probably does not take place at all. The spring epidemic† of

*This rate would doubtless have been greater if two of our batches of mosquitoes had not been fed about 24 hours after a course of plasmochin which had not eradicated the gametocytes, but which doubtless affected their viability.

†Steps are now being taken to ascertain the spring rate of infection in the mosquito in the hills.

(Continued from previous page)

My thanks are due to Major R. Linton, I.M.S., Superintendent, Medical School, Dacca, for allowing me to publish this case note and also to Dr. P. Chakravarty, M.B., D.M.R.E., radiologist, for sending the case to me for investigation.

malaria in the lower hills of the Himalayas is therefore not to be considered as a manifestation of autumn inoculation as it is in Holland, and is a *de tempore* phenomenon, the reverse of the state of affairs in that country.

The schedule below the report shows the detailed observations. In detail it will be seen that only 3 out of 49 mosquitoes taken to the hills, dissected and examined after 10 days had the glands infected with sporozoites and it is significant that these 3 were included in 2 batches (nos. 1 and 2 in the schedule, Table I) that had been kept, except for 2 days‡, after arrival, in a closed room on the south side of a laboratory on which the sun beat down and which was otherwise kept warm by a charcoal fire; the resultant temperature being as shown in Table II where it is contrasted with the temperature at which the other batches, which showed no gland infection at all, were kept, in a room open day and night.

As the required material was not available in the hills the mosquitoes had to be infected in Calcutta§, but this was an advantage in that infection was putatively established in the mosquitoes at the same rate as if they had remained in Calcutta and so one may conclude that it was afterwards that the infection was killed under the conditions of carrying on the observations.

It had been anticipated that if this event should take place, the degenerating parasite would be revealed by 'black spores' in the gut, but, in the sequel, whereas in Calcutta 32.5 per cent of the mosquitoes showed the developing plasmodia as zygotes or oöcysts in the gut wall, in the hills only 1 specimen, or say 2 per cent, showed black spores, so that the balance of the putative gut infection was entirely lost.

Then it was thought possible that the normal infection inseminated in Calcutta might under the conditions in the hills only be arrested and that, on restoring favourable conditions to the mosquito, the infection would forthwith manifest itself. With this in view, 28 of the mosquitoes were, after a greater or less interval, returned to Calcutta and then after another period of from 1 to 5 days examined for parasites. In one of these 28 mosquitoes infection of the glands was seen, while of 24 mosquitoes that remained in the hills all the time 2 developed infection. There was thus no proof that the infection had merely remained in abeyance in the hills.

‡On these 2 days the minimum temperature was 57°F. and the maximum 77°F.

§Some little time had to elapse before they arrived in the hills, the mosquitoes after being fed being usually either despatched the same night to the hills by post or taken by some guardian by train. Batch 1 was exceptional in remaining in Calcutta an extra 24 hours. The journey through the plains takes about 12 hours.

It therefore appears justifiable to say that malarial infection is not possible at all under the conditions prevailing during autumn in the hills.

The development of the insect on the other hand goes on during the cold weather. Larvæ and pupæ were caught in the Balasun river bed; larvæ pupated when kept in the open at Ambootia (3,000 feet); and larvæ and pupæ were

the hills there is practically no autumnal malaria is that the physical conditions debar infection in the mosquito. People can therefore go without mosquito nets with impunity at this season.

Acknowledgments are due to Mr. O'Brien Webb, Manager of Ambootia Tea Estate, for so kindly giving us the hospitality of his administration, as well as privately, for the conduct of this enquiry. They are also due to

VELOCITY, SILT AND LARVAL DRIFT

By D. MANSON, M.B., F.R.E.S.

Chief Medical Officer, Jorehaut Tea Co., Ltd.,
Cinnamara, Assam

Introduction

THE scope of this paper is, as indicated in the title, to enquire into the factors which determine larval drift or infiltration, and to establish their mutual relations.

Since the advent of anti-larval methods of control, a considerable literature has sprung up on the causal factors of larval drift. Although these factors have now been ascertained, little has been done to place this knowledge on a scientific basis, or to follow the action of the various factors for a sufficiently long time to afford definite and conclusive evidence of their relative values.

The importance of velocity and silt as factors in the control of larval breeding places was clearly enunciated by Ramsay in a paper entitled, 'The factors which determine the varying degrees of malarial incidence in Assam tea estates, and the fundamental principles governing mosquito control of malaria in Assam'. Following on this, the writer of the present paper decided, some years ago, to carry out laboratory researches into the relation of velocity to silt and their respective influence on larval life. The results of these experiments were embodied in a paper on 'The control of malaria on a group of tea gardens in the Sibsagar division of Assam: some observations and results'.

This paper was read at the Annual Meeting of the British Medical Association in Shillong on 24th March, 1934.

These researches showed very convincingly that larval death rate was closely correlated to velocity, increasing with the velocity within limits. It was also established that silt did not influence larval death in these laboratory experiments and that pupation occurred at the normal time and adult mosquitoes were hatched out in silty waters.

At that time, Sir Malcolm Watson suggested to me that these laboratory experiments might well be corroborated by actual observations in local permanent waters. This was done and these field experiments have confirmed the laboratory findings and form the subject-matter of this paper.

The field experiments

These were carried out from April 1934 till 31st December, 1935, and are still being continued.

Method of investigation

Velocity.—Velocity of flow in rivers may be measured by several methods. The simplest is the use of a proper velocity meter, which is merely an adaptation of the old water-mill on a very small scale. The machine is geared to

correspond with known velocities and accurate results are easily obtainable.

Such a meter was not available at the time of these experiments and another method was used. A float made of wood, one inch square by one foot deep, was weighted on one end, so as to allow the wood to float with its top end about one inch above the level of the surface of the water. A tennis ball similarly weighted was also used at the beginning but was less successful. As shown in the charts appended, three different observations were made on three rivers widely separated.

In each case, a stretch of river was chosen as straight as possible and clear of any adjoining bays or backwaters along the banks. In every case, the length of the stretch of river chosen was 440 yards, the distance being carefully measured along the river bank.

The float was placed in the middle of the river at the upper end of the quarter-mile and the time of transit to the lower limit was checked by a watch.

It is necessary to repeat here that these stretches of water were straight as it is obvious that velocities would be reduced where rivers bend in their courses. It is also clear that, if velocities affect larval drift, larvæ are more likely to be absent in straight river courses than in sections where the course is tortuous and impeded. It can therefore be postulated that, if larvæ are found in the straight sections at any particular time, they are much more likely to be found in sections of rivers where the course is winding and the banks broken and irregular at the same time. The three charts shown therefore indicate conditions which are least favourable to the presence of anopheline larvæ, under any conditions of flow. Observations were made once a week during the years 1934 and 1935.

It must also be noted here that velocities vary with the distance from the bank and are usually highest in the middle and lowest at the banks.

A float deeper than 12 inches was found impracticable as the varying depths of these monsoon rivers render it impossible continually to alter the apparatus used.

Velocity varies at different depths in the same vertical plane and the velocity of the wooden float would be equal to the mean velocity of the river, when the depth of the float is from 0.950 to 0.927 of the depth of the river.

Such a degree of precision was not attainable in these experiments and the velocities registered must be regarded as slightly above the actual mean velocities in each case. This degree of error is merely of scientific interest and does not vitiate the result of the experiment.

In any case, the surface velocities only are of primary importance in considering the bionomics of anopheline larvæ, as much of their lives is spent on the surface.

Silt

When the velocities were checked, quart samples of river water were collected in wide-mouthed glass containers. The silt was separated by drying off the water and weighed, being calculated as grains per quart.

In addition to velocity, and silt, the charts appended show local rainfall, and the presence or absence of *Anopheles minimus*. As *A. minimus* is the principal vector of malaria in Assam, it has not been considered necessary to record observations on any other anopheline larvæ in these experiments.

Results of experiments

The results of these experiments are given below in tabular form, and show clearly, with the charts in the appendix, the relations between velocity, silt and larval drift.

In chart 3, rainfall is not recorded as exact figures were not available.

CHART 1

From these charts, it will be clearly seen that velocity and silt are closely correlated, silt

In my original paper, read before the British Medical Association at Shillong on 24th March, 1934, the following remark is made:—

'In normal years, the permanent streams and rivers are repeatedly flushed during the monsoon period and the rate of flow is fairly high. In the present year, owing to the deficient rainfall and its peculiar distribution, the normal flush and flow of permanent waters did not occur. The result was that *A. minimus*, which is normally not found in permanent water from the middle of June until late September, was present during the whole period of the monsoon.

During the year in question, 1933, the total rainfall was 72.98 inches only, against an average of 84 inches for this district of Assam. *A. minimus* larvæ were found throughout the monsoon in local permanent waters. From 13th July till 12th August the total rainfall was only 4.93 inches.

CHART 1
 Katonibari T. E.

increasing in fairly definite ratio to the increase in velocity. The effect of local rainfall, whilst also showing some degree of correlation, is not so close, as rainfall in the hills influences the velocity and silt, independently of local rainfall.

Again between 8th and 20th September, 1933, the rainfall was only 0.97 inch.

Malaria was very prevalent and, in one uncontrolled garden in the Sibsagar district, malarial admissions from 1st April till 30th

November numbered 1,857 out of a total admission of 3,034'.

It is further remarked in the same paper:—
'Permanent waters, which are normally free from this species during the monsoon, become potent sources of *A. minimus* activity and constituted reservoirs of anopheline supply additional to the usual epidemic summer breeding resorts. It is very necessary to point out this factor in years of short rainfall in Assam, as so far the importance of permanent waters has not been definitely emphasized'.

It should also be noted that, during this period, the temperature range permits of rapid larval growth and rapid sporozoite formation in infected adult anophelines.

It must not be inferred that *A. minimus* larvæ were present daily during the whole of the periods shown, but they were found on many occasions within these limits, these occasions coinciding with the slack flow between successive spates.

For example at Katonibari, *A. minimus* larvæ were found in the third and fourth weeks of

CHART 2
Hattichungee T. E.

In elaborating any scheme for anti-larval control in Assam, permanent waters must therefore be taken into serious account as auxiliary breeding grounds in years of short rainfall.

This finding must now be amended and amplified in view of very conclusive evidence in the charts that, after the establishment of the monsoon in mid-June, *A. minimus* larvæ are present in permanent waters in the Sibsagar division in years of normal rainfall, at times varying from 8th June to 21st September in one instance and from 15th August in another, according to the rate of flow and the distribution of the rainfall.

August, third week of September, second week of October, third week of November and during December 1935. This larval drift was due to varying velocity of the river during that period, permitting larval ebb and flow.

These results are most important and indicate that larval drift in permanent rivers must be taken into close account in any scheme of anti-larval control. Not only so, but, as has been emphasized, if larvæ occur in these straight stretches of river, their presence in tortuous and ragged channels must be much more common.

The significance of these findings must be pointed out, as recently, Dr. Rice, Assam

Research Officer, has formulated a scheme which sponsors anti-larval control from early January to mid-June. This scheme has obviously been prepared without due knowledge of, and regard for, the basic factors, larval drift and adult migration.

He proposes to leave nature to do all the control from mid-June till the end of the year.

This plan completely ignores the inexhaustible colonies of larval 'unemployed' which line the banks of all permanent rivers for miles outside the relatively tiny zones of control. It forgets the adult anopheline population, hatched therefrom, which are 'on the dole' and are seeking

Adult migration and propagation would proceed during this time without let or hindrance. The result would be intensive anopheline breeding and prevalent malaria.

The danger of such a scheme of control cannot be estimated. It is heralded with the shibboleth of 'the most economical and efficient method of dealing with the malaria problem in Assam'. It remains but to point out that such a scheme can be neither economical, nor efficient; for it is intrinsically unsound as it ignores the basic biological facts of anopheline life. It must also be remembered that, not only the permanent waters as shown, but also many

CHART 3

Nagajanka T. E.

the means to sustain life and to reproduce their species. They must migrate to live. In seeking a blood meal, they are obeying the laws of racial preservation which are common to all, from the lowly *Amæba* to that end-product of nature called, sometimes perhaps optimistically, *Homo sapiens*.

Larvæ carried in by drift would hatch out unchecked and the adults that emerged would seek safer areas for egg deposition in the usual summer breeding resorts.

secondary breeding areas in temporary rain-filled jans, streams and tanks, are full of *A. minimus* larvæ during the months mid-June to November. As a matter of concurrent interest, it may be noted that the highest rate of sporozoite infection in *A. minimus* was found in this district in October, as noted in a paper by the writer. No pre-monsoon control would prevent this invasion.

Any scheme which ignores these factors is bound to fail and, in failing, would bring anti-

larval methods of malaria control into unmerited disrepute.

In this connection, Ramsay has noted that there are many tea estates, especially in Northern Bengal, where the watercourses become completely dried up during the cold weather and where no *A. minimus* can be found for several miles distant from the estates, which yet are invariably intensely malarious during the rains.

The reasons for this finding are now evident.

Can larval drift be nullified?

Sinton has suggested the continuous application of oil as by the use of oil-balls and the use of a floating boom placed across the stream. He found a considerable reduction of larval drift by these means. In his experiments, the rate of the current was stated to be 180 yards per hour and again 200 yards per hour.

These experiments are very instructive and indicate a possible means of control of larval drift in fairly sluggish streams. In Assam conditions, however, the river velocities are very much higher and it would be a matter of great difficulty to carry out similar work. The writer tried screening a small river above a controlled area with closely woven wire-mesh but this barrier was repeatedly washed away during heavy rains.

The present method of control is to oil *A. minimus* areas in permanent water in bamboo enclosures along the banks. This can easily be done and affords the only practical method of larval control in large rivers during the monsoon. It necessitates very close supervision and the constant attention of the anti-larval squad.

Silt

The silt tables show no definite relationship with the presence or absence of *A. minimus* larvæ, and the action of the silt, if a factor in larval bionomics, must be considered after further research. The findings so far corroborate the laboratory results already referred to. Silt is closely correlated to the variations in velocity. Possibly silt may act by causing scouring of the marginal vegetation which affords an anchorage for larvæ.

Summary

Experiments on the velocity of permanent waters, the amount of silt present and the relations of these factors to the larval stage of *A. minimus* are described. The times of larval drift are indicated and the velocities which accompany these larval infiltrations are registered. A note has been made on the effect of local and distant rainfall.

The effects of this larval drift on local anti-larval control measures are fully elaborated. Velocities which exceed the average of 2.04 miles

per hour, the limits being 2.25 miles per hour as highest and 1.375 as lowest, are inimical to larval life in Assam.

This average is approximately the same as those recorded by P. I. De Jesus in the Philippines. He recorded that *A. minimus*, although it prefers slow-moving streams, was also found in temporary rain-pools. He notes that no larvæ were found where the velocity increased to more than 3 feet per second during heavy rains. This corresponds to 2 miles per hour. He also makes an important note that in areas where *minimus* breeding streams dry out during the dry season, malaria is to be expected mostly during the rainy season. This bears out Ramsay's finding in North Bengal.

The use of Sinton's methods of controlling larval drift is commented on, in relation to the velocities recorded.

Charts are shown which indicate the relations between velocity, silt, and larval drift.

Larval drift during the monsoon months of June to October must be taken into account in all schemes of anti-larval control, which are practical.

The danger of non-control during the period of mid-June till mid-November is strongly emphasized.

The scheme of pre-monsoon control only is traversed and found wanting.

The correlation of silt to velocity is noted.

Attention is again drawn to the presence of secondary larval breeding resorts during the monsoon months.

The possibilities of controlling larval drift are discussed.

Acknowledgments

I have to thank the members of the medical staff and Dr. L. R. Dey of the Cinnamara Central Laboratory for their assistance in preparing the charts, and carrying out the routine work involved in these experiments.

A Mirror of Hospital Practice

A CASE OF GAS GANGRENE

By H. W. FARRELL, F.R.C.S.E., D.P.H.
CAPTAIN, I.M.S.

A MALE child, aged 11 years, was admitted on the 2nd June, 1934, with the history of having fallen on his head from a tree 24 hours previously. The patient was unconscious with a temperature of 103°F. and pulse rate 120. He had a simple fracture of the left femur, simple fracture of the left radius and compound fracture of both bones of the right forearm with the proximal end of the right radius protruding through a small clean-cut wound about 3 inches above the wrist. Except for the coma, and a hematoma of the scalp, there was no other evidence of cranial injury. The compound fracture was reduced, the wound cleaned, the arm put up in extension and appropriate attention given to the other injuries. The next day the child was still unconscious with a temperature of 104°F. and the wound on the right forearm appeared clean and healthy both then and on the same evening. The following morning about 6 a.m. the fingers of the right arm were noticed to be discoloured and on opening the dressing it was found that the wound was oozing frothy serum while the surrounding tissues were greatly distended with gas bubbles, the temperature was still high, and the patient unconscious with pulse irregular and barely discernible.

By 9 a.m. the arm was distended with gas as far as the elbow and the skin was greenish-black in colour; there was a most offensive odour. The general condition was considered too bad to attempt operation and the father decided to carry the child home but having gone some miles on foot in the hot sun he changed his mind and carried the child back to the hospital about midday. The gangrene had by then spread to the shoulder with bubbles of gas all over the chest wall and the patient was pulseless and almost moribund.

Injection of anti-gas-gangrene serum was commenced immediately; it was given subcutaneously at the limits of the gangrene and also intravenously. From the time of commencement of the serum therapy, the gangrene did not appear to spread and the general condition improved enormously so that within 24 hours the patient was conscious and able to take drinks; during this time 240 c.cm. of serum had been given, about half of it intravenously and the remainder encircling the limits of the gangrenous limb. The following day (that is on the 5th day from admission) the general condition was considered sufficiently good to justify operation. Under general anaesthesia, the arm was disarticulated at the shoulder joint, the axilla and shoulder were enormously distended with gas, the muscles were greenish-black and friable and the gangrene was found to have spread in the muscle planes much beyond its skin limits; the gas escaped in large quantities and the odour was most offensive. No hæmorrhage whatever occurred during the disarticulation. The gangrenous muscles were then traced; it was necessary to remove the pectoral muscles completely up to their costal origins; the scapular muscles were not so extensively involved and it was possible to retain the scapula by partly denuding it of its muscles; the latissimus dorsi muscle was almost completely removed as well as the coracoid process with its attached muscles. The axillary vessels were tied underneath the clavicle but could not be identified satisfactorily and some gangrenous tissues were included in their ligature. The wound was left open.

The patient stood the operation well, progressed satisfactorily for some time and the wound began to granulate everywhere except where the axillary vessels had been tied; here there was a black slough and marked pulsation was visible; the nerve trunks had not been crushed and appeared to give great pain at the time of dressing the wound. On changing the dressing on the

21st June, the slough gave way and the axillary artery spurted great quantities of blood; fortunately it was possible to grip it digitally while the patient was anaesthetized and it was then tied higher up and the vein, which had begun to bleed during the manipulations, was tied separately with some difficulty as the vein wall was friable; the nerve trunks were then separated, pulled down and crushed.

The wound progressed satisfactorily and was rapidly covered with healthy granulations and the fever disappeared. A week later the temperature rose to 103°F. and some swelling was noticeable at the site of fracture of the femur which so far had not had efficient fixation and was as yet ununited. On the 29th June, under general anaesthesia, the thigh was opened up and an abscess containing thin pus and a large quantity of the same foul gas was found surrounding the fractured end of the femur; there was no gangrene of the surrounding thigh muscles; the abscess was drained and the offensive odour continued for some days. The subsequent progress was uneventful and the patient was taken away against our advice on the 25th July. Some months later it was learned that the wounds had healed and the femur had united but with considerable shortening.

The remarkable improvement following administrations of anti-gas-gangrene serum, and the subsequent formation of a metastatic abscess containing gas at the site of fracture of the femur without any appreciable gangrene of the surrounding muscles are interesting points in this case.

INTRAVENOUS ALCOHOL IN PNEUMONIA

By KRISHNAPRASAD DE, M.B.
Garhbeta, Midnapore

S. T., a postal peon, was attacked with right-sided pneumonia on 11th January, 1936, and was first seen by me on the 15th in the following condition:—

Pain in right chest, distressing cough with rusty tenacious sputum, slight cyanosis, offensive diarrhoea; temperature 103°F., pulse, 20, respiration 36. Lung—lower lobe consolidated, pleuritic rub, bronchial breathing and subcrepitant râles present.

Omnadin (Beyer) 2 c.cm. given hypodermically, and orally an alkali-glucose D drink and a mixture containing Sirolin syrup dimol and digifortis; biphlogiston on chest.

16th morning. Toxæmia supervened, cyanosis increased, pulse 130, respiration 45. Twenty cubic centimetres of a 20 per cent solution of alcohol in normal saline was given intravenously and lower bowel lavage potassium permanganate lotion (1-4,000). Six hours later the patient felt much relieved and had a good sleep.

17th morning. Pain and cough much less, sputum loose, cyanosis and toxæmia less, temperature—101°F., pulse—112 and respiration—32. Patient refused to take any further injection. Crisis occurred on the 18th evening and uneventful recovery took place.

Remarks.—Non-specific stimulation of the defensive powers by omnadin and a specific action of alcohol on the lung (see Baksh and Anderson, *I.M.G.*, December 1935) seemed to have exerted a very beneficial effect on the whole course of the disease. No reactionary rigors were present and temperature was found to be lower on the morning following the alcohol injection.

Indian Medical Gazette

MAY

THE POPULATION PROBLEM IN INDIA

THE population problem in India is a subject that has been discussed many times during the last decade in the editorial pages of this journal. It was not a very popular subject ten years ago. Much of what was written regarding the necessity for controlling the population in India was misinterpreted, and we found that we had raised the bitterest resentment in quarters whence we expected to get whole-hearted support. Vital statisticians took the view that our fears were unnecessary, sanitarians that our suggestions were retrograde, and religious sectarians that we were preaching heresy.

It is not hard to see why it is that any suggestion that the population should be controlled raises such angry opposition. There is a deep-rooted biological instinct, the instinct of self-preservation, that tells man that he should multiply his species until they become so many and so strong that they can banish or control all other animal species and rule the earth; though this has been achieved, the instinct still remains, but is interpreted differently, and it is for the sake of his own particular nation that he thinks it is necessary that he should reproduce his own kind in order that they may be numerically stronger than all others, and as a nation enforce their will upon all other nations; this has never been achieved and those nations who have come nearest to achieving this ideal—if it is an ideal—have not done it by force of numbers but by the development of certain qualities. This nationalized instinct is still unfortunately very prevalent and to-day one sees the paradox of dictators giving prizes for large families within countries and at the same time whining to other nations—or even attacking them—on the grounds of finding an outlet for their surplus population. But we in India have no extra-territorial ambitions, and there is not even this excuse for adopting a misguided policy.

Religious opposition is the easiest to understand and the most difficult to circumvent. Most religions were originally based on reason, but reason applied to conditions that existed a thousand or more years ago and do not exist to-day. Religions were always closely linked with national aspirations and it is natural that the founders should teach their followers to honour the prolific and condemn all means of limiting families. But what was reason a thousand years ago is dogma to-day. The world has moved on and religious teaching must come into line.

It is also easy to see how the opposition of the sanitarian originated. He has been taught to measure the success or otherwise of his work by the rise or fall of the population (or by the fall or rise in the death rate). A severe epidemic visits a province, villages and districts become depopulated, the population falls, and the result is disastrous to the revenues and general progress in the province; this is obviously a 'bad thing', and he argues inversely that an increase in the population must always be a 'good thing'. The subject would make excellent material for a fairy tale. A conscientious but not very intelligent sanitarian who had laboured all his life to increase the expectation of life in India was visited by a fairy god-mother who gave him three wishes. His first wish would not unnaturally be that the expectation of life in India—now 26 years—should be increased to that of England and Wales—about 57 years, and his second that he should live long enough to see the full effects of his first wish; but being of Scottish parentage he was cautious and traditionally reserved the third wish. Had he been wiser he would have used it and wished that the birth rate should be halved, but alas he left it until too late and when he realized the havoc he had wrought he was compelled to use his third wish in asking for a return to the *status quo*.

The ideals of the sanitarian are undergoing re-orientation; they are now rather the saving of human suffering and the avoidance of wastage of human lives than an actual increase in population. The difficulty is that the latter will follow as a natural sequence unless some measures are taken to equalize matters. First of all, however, he must devise new means of evaluating the success of his work; his measure must be the average of the state of health and nutrition in his population and not simply the rise and fall in its numbers.

From the medical point of view there is practically no opposition to population control or to the more particular birth control. The doctor has to attend too often on the poor woman worn out with numerous futile pregnancies, most of her children having died in infancy, or on the ill-nourished child born to parents who are unable to support even themselves on an adequate diet. He feels that people of all classes should have it within their power to control their pregnancies, and that this privilege should not be confined to the rich. This raises a point about which there is frequently much misunderstanding; it is often said that the birth control movement will only lead to control of births in the higher strata of the population and that future generations will be the offspring of the lower strata only, with an accompanying detrimental effect on the race. As pioneers such as Dr. Marie Stopes are always pointing out, the idea of the movement is to combat this very tendency. For many decades the upper

classes in England have used contraceptive measures, and the whole object of the movement is to show to the members of the lower classes how they can do the same in a cheap and effective manner when it is desirable, for medical or other reasons, to do so. Our readers will remember in our January number a paper which we reprinted from *Marriage Hygiene* on a contraceptive method suitable for Indian villagers.

There has been in India during the last ten years a very considerable change in the general attitude towards the population problem; views which we expressed 10 years ago and which were not well received are being repeated with slight variations and additions on all sides, and the dangers ahead are being viewed with alarm and not so frequently referred to as 'Malthusian nightmares'. The Public Health Commissioner with the Government of India in his report for 1933 has again pointed out the dangers of the situation, and although we have already reprinted a large section of his report in our January number we feel that we need not apologize for again quoting a very relevant extract from it :—

There seems little doubt that by 1941, when the next census is taken, the population of India will considerably exceed the estimate of 400 millions given in last year's report. The population problem in India is therefore a real one and, because scepticism still exists in the minds of certain authorities who continue to ignore facts, that problem demands further examination from an angle which, so far as I am aware, has not yet been given sufficient attention. The late Mr. Joseph Chamberlain, at one stage of his political career, spoke of 'three acres and a cow' as providing a sufficient standard of living for the average English agricultural labourer and this famous phrase has been frequently used since as forming a suitable basis on which to found arguments intended to defeat *laissez faire* opposition. Examination of the figures in India gives interesting results. The total land in British India amounts to 667 million acres but of this total only 232 million acres were cultivated and sown, 47 millions lying fallow, 154 millions being culturable but uncultivated, 145 millions being not available and 89 million acres consisting of forests. Even making the ridiculous assumption that the whole 667 million acres of land were available, this works out at only 2.44 acres per head of the population. A more reasonable assumption would be to take the acreage made up of cultivated and sown, fallow, and culturable but uncultivated. These three items total 481 million acres which gives only 1.75 acres per head of the population. But some land must be allowed to lie fallow, an additional proportion must be given over to the cultivation of crops other than food and, during 1933-34, the total acreage under food crops amounted to only 206½ million acres. This gives only 0.72 acre per head of the population in British India and it does not require more than an elementary knowledge of agriculture to realize that it is impossible to provide a sufficiency of food for the present population of India from an acreage of this dimension. It may even be held that were all available cultivable land given over to food production alone, the supply would fall short of reasonable and adequate demand. In order to forestall the usual argument, it can be admitted that the present shortage *might* be met for a short period of years by more intensive methods of cultivation, but that implies the immediate adoption of these intensive methods all over India and to those of us who know the village

ryot, it is difficult to envisage a solution of the problem along those lines. Even supposing that additional supplies were made available in this way, however, the difficulties would only be postponed for a few years, because the increased numbers of the population would rapidly absorb the surplus. Apparently, therefore, the problem of numbers in India is even more acute than before and it is one of such importance to the welfare of this country that it deserves immediate examination and certainly more detailed notice than it receives in paragraphs of this report. Numbers are so intimately bound up with economics that the problem is one which affects every department of Government and every class of citizen. It is a question which will shortly force itself upon the attention of every man and woman in this country: it is hoped that it will receive adequate notice before disaster befalls.

The problem is far from being one with which India alone is concerned and it is a matter that continually comes before the League of Nations' Health Organization. In a paper, by Doctors Burnet and Aykroyd, that appeared in the Quarterly Bulletin of the Health Organization on the relationship of food and public health, there were many references to this question of the adequacy of food supply and the population. They said that there were very clear indications 'that the amount of food at present produced is enormously less than the amount required to provide mankind with a satisfactory diet', and also that 'the existence of surplus stocks and overproduction in general at certain moments in certain countries does not in any way prove that the world produces too much food or even enough to meet the needs of the population'. They qualify this further by saying that 'in an era when great benefits might be derived from an unimpeded distribution of foodstuffs, nations are retiring into voluntary isolation and falling back on their own resources'. 'Transport is perfected within countries; paralysed between them'. They envisage a time, not far distant, when in progressive countries food supplies will be nationalized and all will be assured of an adequate basic diet, or even internationalized—a more distant dream. Before this can come about and whole nations are put on a food ration, they must first be put on a population quota which they must guarantee not to exceed. But this is an Utopian ideal which to-day seems more distant than it did even 20 years ago, and we must return to our own particular problem.

An important paper on this subject was contributed by Colonel Russell, the Public Health Commissioner with the Government of India, and Dr. Raja of the All-India Institute of Hygiene and Public Health; this paper appeared in the October number of the *Indian Journal of Medical Research*. They summarize the position very well, and by way of concluding our remarks on this important subject we feel that we cannot do better than quote them :—

'A human community has something of an organic unity in that its directive force, as represented by its Government, attempts to

shape the activities of the community towards what it conceives to be the common interest. The success or failure of such effort depends largely on the voluntary acceptance by the individual of the measures proposed by the State. The solution of the population problem must, therefore, rest with the people themselves. The problem is essentially one of man's increasing mastery, over his environment; the widest

measure of education is a consequent necessity in order that he may be suitably equipped to face his social and economic difficulties. In the words of Megaw, "What is needed is to educate the rising generation in the hard facts of existence, to show them how the people of other countries have solved their problems and then to let them choose for themselves how they will plan their lives".

ASTHMA

By DHARMENDRA, M.B., B.S.
School of Tropical Medicine, Calcutta

Definition.—The term 'asthma' derived from a Greek word meaning 'panting' is applied to a type of paroxysmal dyspnoea associated with prolonged expiration and wheezing respiration. This type of dyspnoea has to be differentiated from the dyspnoea of cardiac or renal disease, pulmonary new growth, foreign body in the bronchi and lungs, disease of the pleura, etc.

Asthma in India differs markedly from the disease as it is found in the West, and from the textbook description of asthma. It is only rarely that we come across cases of horse asthma, dog asthma, cat asthma, chicken-feather asthma, or pollen asthma.

Mechanism.—There are two main factors in the bringing on of an attack of dyspnoea—(a) bronchospasm and (b) bronchial obstruction caused by a swollen mucous membrane and the bronchial exudate. It is probable that both factors play a part in bringing about the stenosis; in some cases one factor is more marked and in others the other.

Theories.—There are many theories as to how this bronchospasm or bronchial obstruction is brought about. The theories can be grouped under three main headings—the nervous theory, the bronchial obstruction theory and the allergic theory.

(1) Nervous theory. According to this theory the attacks of asthma are considered to be due to bronchospasm caused by an irritable nervous system. This is the earliest theory and was conceived long before the constricting effect of the vagal stimulation on the bronchi was known. Later, when this contracting effect of the vagus stimulation on the bronchi was demonstrated, this theory became very popular. It was believed that asthma was essentially a nervous disease and that the attack depended on a spastic contraction of the bronchial muscles resulting from direct, reflex, or psychic stimulation of the vagus nerve.

In 1903 Brodie and Dixon demonstrated that stimulation of the septal mucosa of the nose

produced bronchial constriction. This finding directed much of the attention to the nose as the causative factor of asthma and at one time it was believed that all cases of asthma were dependent on a reflex set up by some pathological condition in the nose.

(2) There are various views as to how the turgescence of the bronchial mucosa and the secretion bring about the attacks. These views can be summarized as under :

(i) The attack is brought on by the air passage being plugged with viscid secretion resulting from an exudative bronchitis.

(ii) The obstruction is caused by turgescence of the mucous membrane brought on by vasomotor disturbances, this transient oedema of the bronchioles in asthma can be compared to vasomotor rhinitis and angioneurotic oedema in the skin.

(iii) Vascular dilatation and the resulting stiffness of the bronchial mucous membrane bring about a loss of elasticity and motility of the lungs; this interferes with its collapse and gives rise to prolonged expiration. According to this view there is a dilatation of the bronchioles and not a contraction.

(iv) Inflamed mucous membrane or the viscid exudate irritates the vagal nerve endings and reflexly produces a spasm. This theory embodies both the factors—the exudative bronchitis, which is the primary factor, and the resulting spasm brought out through nervous intervention.

(3) Allergic theory. Meltzer (1910) pointed out the similarity between the bronchial constriction in asthma and that seen in guinea-pigs dying of anaphylactic shock. He maintained that asthma was a manifestation of anaphylactic hypersensitiveness in human beings. Wolf-Eisner had already suggested anaphylaxis as the basis of hay fever. As all the facts about asthma and the asthmatics could not be explained by the nervous and the obstructive theories this anaphylactic theory of asthma came to be very popular. But before long it was realized that this manifestation in human beings differed a good deal from the anaphylactic phenomenon as seen in animals. For example, anaphylaxis is always acquired while

asthma is usually inherited; a protein antigen is required to produce anaphylaxis, while substances of any nature can give rise to asthma; and a sensitizing dose is essential in the production of anaphylaxis but not necessarily so in the case of asthma.

To cover this discrepancy a number of terms were coined:—allergy (altered reaction), atopy (strange disease), toxic idiopathies, protein sensitization, protein hyper-sensitiveness, hyper-ergy, idiosyncrasy, etc. Of these the term 'allergy' has become most popular.

According to this theory all cases of asthma are allergic in origin, conditions clinically resembling asthma but not conforming to the conception of allergy (heredity, high blood eosinophilia, sputum eosinophilia, early age of onset, protein sensitiveness, etc.) are grouped under the term 'asthmatic bronchitis' or 'asthmatoïd bronchitis'.

If this position, namely, that only those cases which are allergic in origin are to be labelled 'asthma', is accepted, then in India we have to deal mostly with cases of asthmatic bronchitis because allergic asthma amongst Indians is rare. We, however, take the view that asthma is a clinical syndrome and not a disease. The symptom-complex can be brought about by various factors and a better way is to include all cases presenting this symptom-complex under the term 'asthma' and to classify asthma into the allergic and the non-allergic type. According to this view the causation of asthma can be classified as under:

(A) Allergic.

(a) Allergens gain access to the body from outside.

(i) Ingested. Foods, such as milk, meat, potatoes, eggs, etc.

(ii) Inhaled. Pollens.

Animal emanations, *e.g.*, chicken feather, horse hair, cat hair, house dust.

Industrial dusts, *e.g.*, wheat dust, oil seed, wood dust, toilet powder (orris root), insect powder, moulds and fungi.

(iii) Injected. Animal sera, insect bites and stings.

(iv) Through skin contact. Chemical agents (occupational), physical agents, *e.g.*, heat, cold and light which lead to symptoms from liberation of some specific chemical substance in the body.

(b) Allergens produced in the body.

(i) Septic foci.

(ii) Toxins manufactured in the bowels.

The allergens by themselves may not produce any symptom, there are other important modifying or predisposing factors which have to be taken into account. Vaughan's idea (1928) of a balanced allergic state very well expresses the relationship between these non-specific, non-allergic predisposing factors, *e.g.*, toxic, psychic, environmental, and the specific allergens. When the individual is in a balanced state, an

exposure to the specific allergen may not cause any symptoms, but when the balance has been upset by any predisposing factor, exposure to the same allergen will give rise to symptoms.

(B) Non-allergic.

(1) Reflex, *e.g.*, from the nose.

(2) Chronic bronchitis, bronchiectasis, healed tuberculous foci.

(3) Psychic stimuli in an asthmatic individual may bring on the attack.

It must be added that the ultimate cause of asthma will be found in the particular biochemical make-up of the individual. The most important biochemical changes so far observed in asthmatics are defective liver function, hypoadrenia, and acid-base disequilibrium. A detailed reference to these points is outside the scope of this paper.

Diagnosis.—During the attack the diagnosis is easy. The patient sits up with a forward lean, the sternum is bulged out, the shoulders are raised, and the head is thrown back between the elevated shoulders. The mouth is usually kept open to facilitate breathing. The skin is pale, and may be slightly cyanotic in cases complicated with emphysema. Accessory respiratory muscles are straining to the utmost, specially the sterno-mastoids which stand out very prominently. With all this forced respiratory effort there is very little movement of the chest. Percussion gives a markedly hyper-resonant note and the area of cardiac dullness is decreased. Auscultation reveals the presence of noisy râles and rhonchi which drown the respiratory murmur; the expiration is prolonged and the inspiration is relatively short. During the attacks there may be only the history of the paroxysmal spasmodic attacks of dyspnoea or in long-standing cases there may be prolonged expiration and signs of emphysema.

Differential diagnosis

Cardiac asthma.—The dyspnoea is inspiratory in nature and is definitely associated with muscular effort. The patient bends forward and coughs up a bloody froth. There will be evidence of heart disease, *e.g.*, high blood pressure and arteriosclerosis. There may be a history of cardiac pain or angina pectoris.

Renal asthma.—This is often a pre-uræmic condition. There will be a hypertrophied heart, arteriosclerosis, high blood pressure and there may be retinal changes.

Diagnosis of the clinical type (allergic or non-allergic)

I. *History.*—A carefully taken history helps a good deal in coming to a diagnosis. The following points are carefully enquired into:—

(a) A history of inheritance. This is commonly found in the allergic cases and rarely in the non-allergic cases.

(b) The pre-asthmatic state. A history of having suffered previously from pneumonia,

chronic bronchitis, or pleurisy is very suggestive of the non-allergic type, while a history of a previous attack of urticaria or of dysentery is rather suggestive of the allergic type.

(c) Age of onset. The allergic cases usually start early in life, the non-allergic ones usually start late in life, say after 30 years of age.

(d) Seasonal incidence. Season of incidence throws some light on the possible causative factor. In this connection it is important to remember that the seasonal incidence tends to disappear after the disease has been present for some time.

(e) Association of the attack with a particular place. There is no such association in the non-allergic cases. In the allergic cases this association might give a clue to the offending substance.

(f) Association of the attacks with a particular food. In the non-allergic cases a hearty or indigestible meal might precipitate an attack, but there is no relationship with any particular food. In the allergic cases, at times the patient may be able to name the offending substance, for example, a patient may always get an attack after partaking of fish or egg.

(g) Association with pets, poultry, horses, cows, occupational dusts, etc., have to be noted. In this connection enquiry has to be made if the patient uses feather-stuffed pillows, if there are any factories, gardens, stables, etc., near his residence or place of work, and what occupation he follows. In the allergic cases some association between the attacks and some of these factors may be suspected or be evident. In the non-allergic cases no such association is to be noted.

(h) The condition of the patient's health between the attacks is important. The allergic patients, in the beginning at least, may give a history of clear-cut paroxysms with intervening periods of definite freedom from the disease.

II. *Examination of the blood.*—A total and a differential white cell count together with an Arneth count is done.

(a) A high eosinophile count with an Arneth index below 70 is usually seen in the allergic cases.

(b) A low eosinophile count with an Arneth index above 70 is usually found in the non-allergic cases.

III. *The therapeutic test.*—During the attack of asthma the effects of atropine and adrenalin are tried, beginning with atropine first. A subcutaneous injection of 1/150th grain of atropine sulphate is given at the onset of the attack. Atropine paralyses the vagal nerve endings in the bronchi, and if the attack is due to bronchoconstriction from vagal stimulation the injection will relieve the patient. On the other hand in the allergic cases where the attack is due to direct chemical stimulation of the bronchial muscles, it will have no effect on the attack.

In the allergic cases a subcutaneous injection of 0.3 to 0.5 c.cm. of adrenalin chloride (1 in 1,000 solution) at the onset of the attack cuts it short. Adrenalin will end the attacks in the non-allergic cases as well but atropine works better in these cases.

IV. *The pilocarpine response.*—During periods of freedom from the attacks response of the patient to a subcutaneous injection of gr. 1/20th of pilocarpine nitrate is studied. In the non-allergic cases this small dose of pilocarpine usually produces a marked response in the shape of increased salivation, increased perspiration, flushing of face, and feeling of warmth. In the allergic cases there is a slight or no response.

Confirmation of the diagnosis

(1) A radiological examination of the chest and an examination of the nasal passages may clear up the diagnosis. In the non-allergic cases the examination may reveal the presence of lung damage, nasal polypi, ethmoiditis, etc. In the allergic cases the skiagram of the chest is more or less normal (unless the disease is of very long standing) and the examination of the nose may reveal the presence of vasomotor rhinitis.

(2) The dermal tests might be of help in confirming the diagnosis in the allergic cases. These are based on the fact that those substances, which when inhaled, ingested, or taken into the body by other means, are capable of producing allergic response and will also produce an urticarial weal when brought into contact with the lower layers of the epidermis. There are various methods by which these tests are performed, the dermal, the intra-dermal, the patch test, and the Prausnitz-Kustner reaction.

The diagnostic extracts to be used for testing can be obtained ready-made in the form of pastes in collapsible tubes from Parke, Davis and Co. A rough, though handy, way of making the extract is to macerate a small amount of the substance in N/10 NaOH and to use the supernatant fluid for testing. The standard way to make an extract for diagnostic and therapeutic purposes is to wash the substance with ether, macerate or grind it if necessary, extract it with a buffered saline solution (Evan's solution), filter the extract through a candle and test it for sterility.

Interpretation of the tests.—A positive test is generally of great use, but does not necessarily indicate that a substance giving a positive test is the cause of the illness. Sensitivity to a certain substance may be present but may not be the cause of the symptoms. To incriminate any particular substance there should be some evidence that exposure to that substance actually brings on the symptoms.

On the other hand a negative skin reaction may be obtained in cases of definite clinical sensitiveness.

Utility of the dermal tests.—The tests yield useful information in the allergic cases where a specific allergen is responsible for the attacks, e.g., any particular food, animal emanations or dust.

They are no use in the allergic cases dependent on toxins, absorption from the gut or in the non-allergic cases.

TREATMENT

Treatment of the acute attack

(a) Drugs. There are three drugs commonly used to control the attacks—atropine, adrenalin and morphine-atropine. Atropine paralyses the vagal nerve endings and has a stimulating action on the respiratory centre. A subcutaneous injection of atropine sulphate gr. 1/100 to 1/150 given at the beginning of the attack cuts it short when it is due to bronchial spasm caused by vagal stimulation.

Adrenalin stimulates the sympathetic nervous system and dilates the bronchi. An injection of 0.3 to 0.5 c.cm. of a 1 in 1,000 solution adrenalin chloride given at the beginning controls the attacks. Adrenalin should be given in small doses and in the beginning of the attack. If neither atropine nor adrenalin relieves the patient an injection of morphine gr. 1/6 to 1/4 with atropine sulphate gr. 1/150 should be given. Morphine should be used only sparingly but should not be withheld when it is definitely called for. Only a small amount is to be used; big doses are unnecessary and harmful—unnecessary because morphine has no dilating effect on the bronchi and harmful because the cough reflex may be abolished and the patient may be drowned in his own sputum.

In status asthmaticus where the attack has continued for days together Hurst advocates continuous administration of adrenalin. After the initial injection of adrenalin, the needle of the syringe is constantly kept in place and one or more minims of adrenalin solution are injected every 15, 30 or 60 seconds, according to the reaction of the patient. This procedure can be continued for half an hour or longer. For severe cases Bray (1934) recommends a combination of adrenalin, morphine and atropine administrations. He takes two solutions, (1) adrenalin chloride solution 1/1,000 and (2) a solution containing morphine sulphate gr. 1/4, atropine sulphate gr. 1/100, and adrenalin chloride solution minims x. Of the solution (1), one minim is injected every half to one minute and of the solution (2), one minim is given every fifth minute till the spasm is relieved or till all the ten minims are exhausted.

Graeser and Rowe (1935) have used adrenalin inhalation to cut short the attack. A 1 in 100 solution of adrenalin chloride is used in a specially-made inhaler.

(b) Other drugs. Aspirin is of value specially in the cases where atropine injection affords relief. Caffein stimulates respiration and relieves fatigue. The ordinary A. P. C. powder (aspirin, phenacetin and caffein) works very well in aborting attacks which are not very severe. Ephedrin may be of some use in the mild attack, but its real value is in prophylaxis only. Asthma powders, cigarettes and sprays have no place in the treatment of acute attacks. In mild attacks they afford relief to some people but to others the fumes from the powders and cigarettes may irritate the bronchial mucosa.

The main constituent of powders and cigarettes is stramonium leaves to which saltpetre is added to aid combustion. Asthma sprays contain atropine, cocaine or adrenalin in different combinations.

Iodides are of value in liquefying the bronchial secretion and so making the cough more effective. A mixture containing iodides, tincture ephedra vulgaris minims x to xxx, and some anti-spasmodics (tincture lobelia æth. minims 10 to 20, tincture stramonium minims 10 to 20, tincture belladonna 5 minims, extract kuth liq. 10 to 30 minims, etc.) is given regularly. The following mixture works quite well:

R

Potassii iodidi	..	gr. 5
Sodii bicarbonatis	..	gr. 10
Tincturis stramonii	..	℥ xv
Tincturis lobeliæ ætheris	..	℥ xv
Tincturis ephedrae vulgaris	..	℥ xx
Spiritus chloroformi	..	℥ x
Aquam	..	ad oz. 1

One ounce every four hours.

General measures

(1) A purgative should be given at the beginning, calomel followed by saline does very well. Later, a daily dose of a laxative should be used to keep the bowels open.

(2) In cases where the attack is known to have followed a heavy or indigestible meal or some special food, an emetic should be given. In children the emesis may be produced by tickling the throat. Big doses of sodium bicarbonate, table salt or $\frac{1}{2}$ ounce doses of vinum ipecac. may be used to produce vomiting. Vomiting not only unloads the stomach but also loosens and brings out the bronchial secretions.

(3) For the first 24 to 48 hours the patient should be starved and, after that, easily-digestible foods should be commenced. During the first 24 to 48 hours when no food is allowed sufficient fluids and glucose should be given to the patient, in case he does not take enough fluids by mouth they should be administered per rectum (glucose-saline enema). In case of exhaustion stimulants, e.g., tea, coffee and brandy, should be given.

Treatment between the attacks

I. In the allergic cases where some specific cause is found.

(1) If possible the substance should be avoided. Foods that disagree may be eliminated and when the allergy is due to some occupational factor the occupation if possible should be changed. Pets can be removed and cotton can be used to stuff the pillows in place of chicken feathers, etc. It is very difficult to avoid dust, unless a dust-free chamber or a face-mask is used; residence in the hills above 4,000 feet high excludes most air-borne allergens.

(2) In cases where avoidance is impracticable, for example, where sensitization to multiple foods exists or where it is not possible to change the occupation, the treatment lies in trying to desensitize the patient against the allergen. In affecting desensitization two routes are available :

(i) Desensitization with gradually increasing doses of the extract of the substance given subcutaneously.

(ii) In the case of foods, oral administration of minute but gradually-increasing doses of the food in question, together with dilute hydrochloric acid.

(3) In addition to avoidance or desensitization any obvious endocrine defect or any infected or pathological condition of the respiratory or gastro-intestinal tracts should be treated.

II. In the allergic cases where no specific cause is found, and in non-allergic cases :—

(a) Treat any infection of the gut, e.g., *Entamoeba histolytica* infection, by emetine or carbarsone, hookworm infection by tetrachlorethylene, or by the preparation of an autovaccine to confer immunity against pathogenic organisms isolated from the stools.

An acid-pepsin mixture is of great help when there is evidence of hypochlorhydria. This is specially useful in children as cases of allergy of alimentary origin are most common at this age. The patient should be kept on a more or less vegetarian diet, meat and fish being cut down to a minimum.

The liver should be well looked after. An acid liver mixture after meals and a weekly dose of calomel followed by saline should be given. In order to improve the proteopexic function of the liver which depends on its glycogen reserve Oriel recommends 2 to 4 ounces of glucose to be taken daily in divided doses. Glucose may be taken with meals or dissolved in water and flavoured with orange or lemon juice, it can be taken morning and evening on an empty stomach. Like hydrochloric acid, glucose acts very well in children and both these medicines can be combined in one mixture.

(b) A thorough search should be made for any focus of infection in the teeth, tonsils, sinuses, bronchi, etc. Infective foci which can be removed should be dealt with surgically.

When the source of infection cannot be removed, an autovaccine prepared from organisms isolated from the focus should be used. Operative measures on the nose are not always successful, because the nasal condition may not be the cause of asthma, both the conditions may have a common causative factor or one condition may have no connection with the other.

(c) Drugs. A mixture containing iodides, antispasmodics (such as belladonna, stramonium, lobelia, kuth, etc.), arsenic (Fowler's solution), tincture ephedra vulgaris and sodium sulphate should be given regularly.

R

Potassii iodidi	..	grs. 5
Liquoris arsenicalis	..	℥ iii
Tincturis belladonnæ	..	℥ v
Tincturis lobeliæ ætheris	..	℥ x
Tincturis ephedrae vulgaris	℥	xv
Sodii sulphatis	..	grs. 60
Aquam	..	ad oz. 1

One ounce three times a day.

(i) Patients who suffer from nervousness or loss of sleep should get some sedatives, e.g., bromides, luminal, medinal.

(ii) Patients worried by irritating nocturnal cough should get a cough linctus at bed time. Linctus paregorici or a linctus containing one drachm each of syrupus virginii pruni and syrupus codeini phosphatus and fifteen minims of tincture of stramonium should be used.

(iii) When there is excessive expectoration creosote inhalation in a Burney-Yeo inhaler and a stimulant expectorant mixture should be given.

(d) Endocrine dysfunctions should be treated by adequate means. In case of thyroid deficiency, dried thyroid gland can be given by mouth; no other gland extract is active when given orally. Ephedrine hydrochloride may be given by mouth for adrenal insufficiency. Soamine injections are useful in toning up the endocrines.

(e) Non-specific protein therapy. The object of this form of treatment is to exhaust the sensitivity of the patient. Cecil (1935) thinks 'the most important function of the foreign protein reaction is the mobilization of immune bodies in the circulating blood'. Mackenzie and Frihbauer (1927) have shown that in rabbits, who were previously injected with horse serum but in whom the antibody to horse serum had disappeared, subsequent injections of chicken serum caused antibodies to horse serum to reappear. Peterson and others (1923) have shown that very small doses of peptone caused a lessened permeability of the endothelium. Hektoen (1935) believes that in the reaction to non-specific protein therapy important processes take place in the capillary walls and in the reticulo-endothelial system.

Protein therapy should not be used in presence of active or quiescent pulmonary tuberculosis, cardiac or renal diseases, during pregnancy, in cases of exhaustion and in chronic alcoholics.

There are a number of substances which have been used for the purpose of non-specific therapy :—

(i) Peptone. Auld (1918, 1920, 1925 and 1928) has introduced the use of peptone and serum peptone. Peptone is usually given intramuscularly in 7½ per cent solution; it may be given intravenously in 5 per cent solution. The intravenous administration is not considered safe by some. The initial dose is 0.3 c.cm., subsequent doses are gradually increased till a dose of 1.5 c.cm. is reached, and this dose is repeated about half a dozen times. Injections are given every third day to begin with, then the interval is gradually increased to seven days. In resistant cases Auld advises the use of serum peptone which is prepared by incubating the serum of the patient with agar and peptone.

(ii) Auto-hæmotherapy. Kahn and Emsheimer (1916) introduced the use of autogenous defibrinated blood for the treatment of asthma. Later, whole blood and serum have been successfully used for the same purpose. The initial dose is 2 c.cm., the dose is gradually increased to 10 c.cm. The interval is 2 days to begin with and it is gradually increased to 7 days with the increase in the amount of the blood injected.

(iii) Schiff introduced injections of whole or skimmed sterilized milk. The milk is sterilized in a rubber-capped bottle by boiling for one hour. Injections are given 3 times a week, starting with 0.5 c.cm. and increasing by 0.5 c.cm. each till a dose of 3 c.cm. is reached. Larger doses, 5 to 10 c.cm., have been recommended by others.

(iv) T. A. B. vaccine has been used intravenously. The initial dose is 15 to 25 million organisms of each; the dose is increased to 50, 75 and 100 million organisms, and then by 100 millions each time up to 500 millions. The injections are given twice weekly.

(v) Sulphur. One to two c.cm. of a 1 per cent suspension of sulphur in olive oil has been recommended by van Leeuwen (1932) for intramuscular injection. The injection gives rise to a local painful reaction and constitutional symptoms in the way of fever, malaise and headache. When the reaction has passed off a reduced dose may be given.

It is better to start with 0.5 c.cm. and gradually increase the amount according to the severity and duration of the reaction, the interval may be between 5 to 7 days.

(vi) Tuberculin. van Leeuwen and Varekamp (1921) introduced the treatment of asthma with tuberculin. The initial dose varies according to the reaction obtained with the von

Pirquet test. In very sensitive cases, the initial dose may be as small as 1/100,000,000 to 1/10,000,000 milligramme. In less sensitive cases the initial dose can be 1/1,000,000 milligramme. The dose is gradually and cautiously increased and the injections are continued for months or even years.

(vii) Gold salts have recently been used in the treatment of asthma. Banzsky (1935) attributes the benefits derived from these salts to their general tonic effects and specific tonic effects on the vegetative nervous systems.

(viii) Various other substances such as cobra venom, parasitic extracts, mixed coliform vaccine, influenza vaccine and turpentine have been used for the purpose of non-specific therapy.

(f) Breathing exercises. The patient is in the habit of using the upper part of his chest only for respiration and the purpose of the exercises is to teach him to use the lower part of the chest and the diaphragm. Livingstone and Gillespie (1935) report good results with breathing exercises. The patient is told to take a short inspiration through the nose and then make a long expiration through the mouth, with a whistling or hissing noise; this concentrates the attention on the expiratory phase. During expiration the epigastrium must sink in to ensure that the diaphragm rises in the chest. The exercises should be done for 10 to 15 minutes twice daily. It is reported that with their use the patient may even avoid an on-coming mild attack.

Medical News

SECOND INTERNATIONAL CONGRESS FOR MICROBIOLOGY

LONDON, 25TH JULY—1ST AUGUST, 1936

THE Congress will be officially opened on Saturday evening, the 25th July, 1936. This will be followed by official receptions by His Majesty's Government, by the Royal Society and other societies. Excursions and visits to important institutes and laboratories have been arranged.

Already 20 workers belonging to the Medical, Veterinary and Biological sciences have signified their desire to take part in the Congress. Prospective members are requested to communicate, without delay, either with Dr. A. C. Ukil, Secretary, Indian Committee of the International Society for Microbiology, All-India Institute of Hygiene and Public Health, 21, Chittaranjan Avenue, Calcutta, or directly with Dr. R. St. John-Brookes, Honorary General Secretary, Second International Congress for Microbiology, Lister Institute, Chelsea Bridge Road, London, S.W.1, England, for a copy of the Registration Form and the Programme and to forward the membership fee of £1 sterling to Dr. J. T. Duncan, Treasurer, Second International Congress for Microbiology, London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1. Members should also intimate the Honorary General Secretary in London whether they would be accompanied by ladies.

The headquarters of the Congress will be located at the University College, Gower Street, London, W.C.1, where the scientific meetings will also be held. Messrs. Thos. Cook and Sons, Ltd., of Berkeley Street, London, W.1, the American Express Co., Inc., of 6, Haymarket, London, S.W.1, and Dean and Dawson Ltd., of 7, Blandford Square, London, N.W.1, have been appointed official Travel Agents of the Congress. Information as to special travel facilities, hotels in London, etc., may be obtained on application to these firms in London or at any one of their respective branches or agencies in Great Britain or abroad.

In accordance with the statutes of the Society communications may be made to the Congress in English, French or German. The Honorary General Secretary will be glad to hear from any prospective member who desires to take part in the general discussion on any of the prescribed subjects. All openers of discussions and subsequent contributors must forward to the Honorary General Secretary, Dr. R. St. John-Brookes, before 1st April, 1936, abstracts of their statements for incorporation in a special brochure available at the opening of the Congress. These abstracts are strictly limited to 600 words in case of openers and to 300 words in case of subsequent contributors. Openers will be limited to 20 minutes, invited contributors to 15 minutes and speakers in the general discussions to 10 minutes, at the President's discretion. It is hoped that interested workers of the Medical, Veterinary and Biological sciences will take advantage of this opportunity for making personal contacts between experts assembling from all over the world.

PROVISIONAL PROGRAMME

Sections

1. General Biology of Micro-organisms.
2. Viruses and Virus diseases in plants and animals.
3. Bacteria and fungi in relation to disease in man, animals and plants.
4. Economic Bacteriology. (Soil, Dairying and Industrial.)
5. Medical, Veterinary and Agricultural Zoology and Parasitology.
6. Serology and Immunochemistry.

7. Microbiological Chemistry.

8. Specific immunization in the control of human and animal diseases.

EXTRACT FROM PROCEEDINGS, COUNCIL OF STATE, 6TH MARCH, 1936

THE Honourable Khan Bahadur Dr. Sir Nasarvanji Choksy (Bombay: Nominated Non-Official): Sir, it is a matter of satisfaction that the gloom that pervaded the previous budgets has to some extent been dispelled by the two budgets which the Honourable the Finance Member has presented to us. Apart from that, Sir, my special thanks are due to him for implementing the proposals contained in the resolution which this House passed last session with regard to the Report of the Drugs Enquiry Committee. I am glad that the sum of Rs. 30,000 has been sanctioned to initiate the work in the Bio-Chemical Section of the Central Laboratory at Calcutta; as also in the Bombay Presidency where the Haffkine Institute is about to undertake a similar enquiry. This is just a beginning, but I do hope that as time goes on, more money will be found for these objects that will be for the ultimate good of the population. With regard to the grant of Rs. 10 lakhs to the Indian Research Fund Association for improvement in the conditions of village life and rural population, it has been laid down that the amount shall be mainly devoted to schemes connected with the prevention and treatment of malaria.

Previous speakers have already alluded to the subject and on more than one occasion I have brought it up before this House. All that I would say is that rural uplift—whatever funds may be spent upon it through Imperial or other channels—will be of no use unless the health of the population is conserved in the first instance and unless malaria-ridden tracts are freed from this scourge. Research will no doubt be directed to the prevention and cure of malaria; these researches will take considerable time, but we possess in the meanwhile a remedy for immediate use. I see no reason why it has not been fully availed of.

Sir, in a resolution that I moved in this House two years ago I referred to the use of the remedy that was cheaper than quinine, equally efficacious and the manufacture of which did not involve as much expense as quinine. We have known for a number of years that the cinchona plant from which quinine is prepared is very delicate and besides requires the optimum of conditions for its growth. I then pointed out that there were other species of cinchona that were hardy and capable of cultivation in ordinary climates. The alkaloids derived from those are being prepared at present on a small scale in Madras plantations. It has been named *totaquina* and consists of about 25 per cent of quinine combined with other alkaloids. Government once held large stocks of quinine; and over 60,000 lbs. have been given to the provinces for free distribution, in addition to their normal free distribution and more about 150,000 lbs. have been retained as a reserve. But, Sir, there exist vast areas in this country where the hardier species can be planted. I regret, however, to say that the matter has not been explored as it should have been ere long before. The time has arrived when the Imperial Council of Agricultural Research should be entrusted to take up the cinchona question. This body alone will be able to carry out further research if required and perhaps may be able to find something better than *totaquina*, in case this drug is not eventually found to be as efficacious as has been hitherto declared. I am at a loss to understand the policy which has dictated the cultivation of cinchona in India. May I invite the attention of the Honourable the Finance Member to the November 1935 issue of the *Indian Medical Gazette*, where the whole quinine policy has been fully discussed? It was shown therein that India has been lagging far behind other civilized countries in the production of a remedy that is of immense value to the masses. Look,

for instance, at Italy. It has vast plantations in her African colonies and within two or three years it will not only be self-sufficient but will be exporting quinine. And here with our vast resources of soil, climate, etc., we have to depend upon the mercy of a foreign confederation to supply us with by far the most vital necessity for ensuring good health. It is not that the manufacture and sale of quinine has been unremunerative! Then I should like to ask why we stand where we do in this regard?

Next, Sir, I come to the question of schemes for rural uplift. Numerous questions are involved in it and it is not by a little scheme here and a little scheme there that rural uplift can be made to achieve results. The first consideration is that India is beset with great difficulty owing to the fragmentation of holdings. Unless and until these holdings are consolidated there can be no improvement—not by legislative action—but by mutual and friendly adjustment and co-ordination among those concerned. Punjab has already demonstrated the feasibility of such consolidation. Another scheme of rural uplift which can well be copied is that associated with the name of Mr. Brayne. That has been adopted also in the Punjab and has done immense good. I therefore say, Sir, that the resources which have been placed at the disposal of the Provincial Governments should not be frittered away in small schemes here and there that are not likely to show results or prove attractive and useful. They should be directed to larger schemes in one or two districts that are likely to strike the imagination of the people with their utility and adaptability and serve as fruitful models. It is to be hoped that when the reports of last year's grant are received and new schemes are suggested, the Honourable the Finance Member by exercising his rights over the grant will see that those schemes are of practical benefit.

INTERNATIONAL UNION AGAINST TUBERCULOSIS

PRESS NOTICE

THE Xth Conference of the International Union against Tuberculosis will meet in Lisbon, from 7th to 10th September, 1936, under the chairmanship of Prof. Lopo de Carvalho, President-elect of the International Union. The discussion will be limited to three main subjects: Biological subject: *Radiological aspects of the pulmonary hilum and their interpretation*, opening report by Prof. Lopo de Carvalho (Portugal); Clinical subject: *Primary tuberculous infection in the adolescent and the adult*, opening report by Dr. Olaf Scheel (Norway); Social subject: *The open case of tuberculosis in relation to family and domestic associates*, opening report by Drs. Ch. J. Hatfield (United States) and D. A. Powell (Great Britain). Ten speakers, selected in advance from a list presented by the 44 countries belonging to the Union, have been designated to open the discussion on each of the questions on the agenda.

The Organization Committee of the Conference has prepared a very attractive programme of receptions and excursions; the latter will enable members of the Congress to visit the chief anti-tuberculosis institutions as well as the most picturesque scenery in various parts of Portugal.

Members of the International Union are invited to take part in the Conference free of any contribution fee. They may forward their application through the King George Thanksgiving (Anti-tuberculosis) Fund or directly to the Organizing Committee in Lisbon, at the following address:

Organizing Committee of the Xth Conference of the International Union against Tuberculosis
Assistencia Nacional aos Tuberculosos Avenida 24 de Julho, Lisbon (Portugal).

Persons who are not members of the Union and who wish to take part as 'Members of the Conference' must forward their application, together with a contribution

of 200 escudos (approximately 125 French francs), exclusively through the medium of—

King George Thanksgiving (Anti-tuberculosis) Fund, Talkatora Road, New Delhi.

HUNTERIAN SOCIETY. GOLD MEDAL FOR PRACTITIONERS

ANY registered general practitioner resident within the British Empire is eligible to compete and the medal, which is of gold, is awarded annually to the writer of the best essay on a subject selected by the Society.

Competitors—men or women—must be engaged in general practice and essays should be sent in by 31st December.

The essay must be unpublished and original, and be based on the candidate's own observation, but it may contain excerpts from the literature on the subject, provided that reference be made to the articles from which they are taken.

A copy of the rules and any further information can be obtained on application to the Honorary Secretary, Mr. Arthur Porritt, 27, Harley Street, W.1.

The subject selected for the essay is, for 1936 'Rheumatoid Arthritis—its diagnosis, treatment and end results'.

1937 'The Prognosis and Care of Heart Disease in General Practice'.

For last year's medal, essays were sent in from all parts of the Empire on the 'Conduct of Midwifery in General Practice'. The prize essay was written by Dr. Francis Bennett, M.D., Ch.B., New Zealand, Christchurch, New Zealand, who has been awarded the Gold Medal for 1935. This is the first time the medal has been awarded to a practitioner resident outside Great Britain.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL

THE following students are declared to have passed the D.T.M. Examination, session 1935-36.

Passed

(Arranged in alphabetical order)

1. Shyama Pada Banerjee, M.B. (Cal.), Medical Officer in charge, Burge Memorial Charitable Dispensary, Midnapore.
2. Phanibhusan Basu, M.B. (Cal.), D.P.H. (Cal.), Private Practitioner.
3. Jashvant Tripurashanker Bhatt, M.B., B.S. (Bom.), Private Practitioner.
4. Profulla Kumar Bose, L.M.P. (Burma), L.T.M. (Bengal), Private Practitioner.
5. Debi Pada Chakraverty, L.M.F., L.T.M. (Bengal), Medical Officer in charge, Singell Tea Estate Hospital, Kurseong.
6. Abdul Mumith Chaudhury, M.B. (Cal.), Civil Assistant Surgeon, Government of Assam.
7. Nihar Ranjon Chowdhuri, L.M. & S. (Rangoon), Private Practitioner.
8. Doraisamy Chelliah Daniel, L.C.P. & S. (Bom.), L.T.M. (Bengal), Sub-Assistant Surgeon, Burma Railway—Awarded the 'Chuni Lal Bose' Gold Medal, 1936.
9. Bibhuti Bhushan Das, M.B. (Cal.), Honorary Pathologist, Howrah General Hospital.
10. Madhusudan Das, M.B., B.S. (Patna), Private Practitioner.
11. Pruthwinath Das, M.B., B.S. (Patna), Private Practitioner.
12. Jyotirmoy Das Gupta, M.B. (Cal.), D.P.H. (Cal.), Bacteriologist, Calcutta Corporation.
13. Shivearn Singh Datta, M.B., B.S. (Punjab), Assistant Surgeon, Sibi, Baluchistan.
14. Saroj Bandhab Ghose, L.M.P. (Assam), Sub-Assistant Surgeon, Government of Bengal.

15. Ashutosh Ghosh, M.B. (Cal.), Private Practitioner.
16. Ban Behari Lal Gupta, M.B., B.S. (Lucknow), Private Practitioner.
17. Gursaransingh Hazuria, L.C.P. & S. (Bom.), Sub-Assistant Surgeon in charge, Laboratory Civil Hospital, Quetta, Baluchistan.
18. Muralidhor Kundu, L.M.P. (Burma), L.T.M. (Bengal), Private Practitioner.
19. Maharaj Narain Mathur, L.M.P. (C. P.), L.T.M. (Bengal), Pathologist, Victoria Hospital, Ajmer State.
20. Kulamani Misra, L.M.P. (B. and O.), Private Practitioner.
21. Nripathinath Mukerjee, M.B. (Cal.), Private Practitioner.
22. Valandai Deivasikamony Paramasivam, L.M.P., L.M. & S. (Hyderabad), Assistant Pathologist, Osmania Hospital, Hyderabad (Deccan).
23. Praja Mokkhavesa, M.B. (Chulalongkorn University, Siam), Private Practitioner.
24. Salahuddin Ahmad, M.B. (Cal.), Civil Assistant Surgeon, Government of Bihar and Orissa.
25. Sardar Ali, M.B., B.S. (Punjab), Medical Officer in charge, Shitagarh Dispensary, Dist. Multan.
26. Nirmal Chandra Sen, M.B. (Cal.), Private Practitioner.
27. Amalendu Sen Gupta, M.B. (Cal.), Private Practitioner.
28. Narayan Prasad Sinha, M.B., B.S. (Patna), Medical Officer in charge, Educational Hostels, Patna.
29. Shailendra Kumar Sinha, M.B., B.S. (Patna), Private Practitioner.
30. Kantilal Maneklal Shah, L.C.P. & S. (Bom.), L.T.M. (Bengal), Private Practitioner.
31. Nilkanth Balkrishna Tembhekar, L.M.P. (C. P.), Assistant Medical Officer, Barkui Hospital.

Current Topics

Results and Dangers in the Treatment of Amœbiasis. A Summary of Fifteen Years' Clinical Experience at the Mayo Clinic

By P. W. BROWN, M.D.

(Abstracted from the *Journal of the American Medical Association*, Vol. CV, 26th October, 1935, p. 1319)

THERE have been numerous reports praising or condemning various drugs, pessimistic and optimistic reports on the possibilities of curing the disease, presentations of results of administering drugs based on insufficient experimental or clinical data, and warnings, possibly unduly fearful, of the danger of using different drugs. An outstanding contribution to the chemotherapy of amœbiasis has come from the group headed by Leake, Reed and Anderson. It is from such critical studies that not only facts in regard to present drugs but also possibilities of developing new and better ones are obtained. Most workers in this field have long since agreed that emetine in safe amounts fails to cure more than half the cases of amœbiasis, and that even doses to the point of toxicity often fail. The organic arsenicals seem definitely established as more effective amœbiocides, although since arsenic is a well known poison there has been the search to obtain an effective but safe preparation. At present it would seem that there will always be some risk in the use of any effective arsenical because of occasional individual sensitivity. The dose may be safe in most cases, and experiments on animals indicate a wide margin of safety; but it must be remembered that arsenic or any other active drug is a potential poison. One should therefore always have respect for such preparations and use them cautiously.

The oxygenated quinolines have been the third chief type of drugs used in the treatment of amœbiasis. Some early reports on chiniofon, introduced as yatren, were most enthusiastic, and in the twelve years in which it has been used its worth has been established. More recently, the administration of vioform has been suggested, as experimentally it was found to be very effective. Too short a time has elapsed, however, to establish its final rating. An even more recent drug for the treatment of amœbiasis is diiodohydroxyquinoline, regarding which only a few scattered but encouraging reports are available.

For this period of fifteen years, data on the treatment of amœbiasis in 834 cases are obtainable. In 523 of these cases, information as to results of treatment was secured later. This group of 834 cases comprises a large part of the cases in which a diagnosis of amœbiasis has been made in this period. To facilitate

analysis of so large a group, the first section of this paper will deal with some of the more commonly used drugs in this fifteen-year period, with particular emphasis on reactions; the second section will relate results of treatment.

SECTION I: COMMONLY USED DRUGS AND THEIR REACTIONS

Since ipecac, with its later derivatives emetine hydrochloride, bismuth emetine iodide, auremetine, and the short-lived preparations alcresta, adsorbed emetine and propylcephaline, is the oldest specific drug used in treating amœbiasis, it is naturally the one about which much has been written. Ipecac has dropped out of the armamentarium largely because of the great difficulties encountered in maintaining adequate dosage. Of thirty-six patients at the clinic who received ipecac, 50 per cent suffered severe nausea and vomiting so that hospitalization always was necessary (table I). Even as late as 1927 and 1928, two patients who were resistant to other forms of treatment received ipecac. It seems ironical that ipecac at present is remembered only for its pioneer rôle in the treatment of amœbiasis.

Bismuth emetine iodide continues to be in some favour, especially in England. It too, however, has the disadvantage of frequently causing nausea and vomiting. In the first seven years of the fifteen, thirty-five patients with amœbiasis were given it (table I); its use was then discontinued, however, in favour of emetine, provided any form of emetine was indicated. Bismuth emetine iodide has the advantage that it can be administered orally, which makes its use advisable in some cases.

Emetine hydrochloride has seemed to be a standby through this entire fifteen-year period. With the advent of treparsol and acetarsone (stovarsol), however, its use decreased somewhat, but it resumed an active rôle in the treatment of amœbiasis in conjunction with treparsol. Ever since Sir Leonard Rogers' vivid report (1912) of his first three cases in which emetine hydrochloride was administered, no worker in this field has failed to marvel time and again at one of the therapeutic miracles in medicine: the prompt response of active and acute amœbiasis to 0.19 gm. or 0.26 gm. (from 3 to 4 grains) of this drug. At the clinic, emetine hydrochloride has always been administered subcutaneously, and it is well to note that much undue local reaction is avoided by observing care in injecting it subcutaneously; it is not injected intramuscularly or intradermally, and we see no need of intravenous administration.

Naturally, with the widespread use of emetine there soon appeared discouraging reports about its failure to

effect a cure in more than half of the cases. Occasional reports also appeared of neuritis or palsy, myocardial injury, profound local reactions at the site of injection and, finally, deaths associated with its use. I have been able to find reports of ten deaths attributed to emetine in the period from 1912 to 1935. The United States Bureau of Vital Statistics has no records of death due to emetine poisoning in the United States, although there are two or more reported in the literature. An article by Chopra and Ghosh in 1922 quoted Hall and Dalimer as each reporting three fatal cases. Unfortunately the references were omitted, and I can find only Dalimer's article in 1917, quoting in turn two cases of emetine neuritis or palsy. By no means is there any intention to minimize these tragedies, yet with the millions of injections this small number of untoward reactions is extraordinary. In these ten fatal cases the dose received ranged from one dose of 0.02 gm., given to a child aged 2 years, who died very suddenly after the injection, to 2.64 gm. administered in the course of eight weeks. Leibly's case (1.28 gm. in eight weeks, equivalent to 34 mg. per kilogram) and Levy and Rowntree's case (1.74 gm. in eighteen days, equivalent to 25 mg. per kilogram) are the only two cases in which I find data as to the dose per kilogram of body weight. The other seven patients received 1.07, 1.44, 1.04, 1.52, 1.08, 1.88 and 0.48 gm. in periods of from two to eight weeks.

In the series at the clinic of 554 patients who received emetine (table I) the usual dose ranged from 0.24 to 1.17 gm., the latter dose being given in a month's time and being not more than 17 mg. per kilogram. In the past seven years the usual dose has been from 0.39 to 0.65 gm. in any one month, or about 9 mg. per kilogram (estimating an average normal of 70 kg.). There have been no deaths in these 554 cases except of one patient who was moribund on admission as a result of peritonitis from a ruptured abscess of the liver; death occurred seventy-two hours later. He had received 0.39 gm. of emetine in that time.

The not tragic but nevertheless distressing complications of emetine therapy are peripheral neuritis or palsy and cardiovascular disturbances. It is well to remember that the effect of emetine is cumulative and that it is eliminated slowly just as is the arsenic in acetarsonne and carbarsone. In 1920 Mattei demonstrated this fact and in one case found emetine present in the urine sixty days after an eight-day course of 0.48 gm. of the drug. No doubt not all deaths have been reported, and certainly many of these less serious reactions have not. I have found thirty-seven such cases in the literature in which the average amount of emetine given was 1.0 gm., eight of the patients having been poisoned by 0.65 gm. or less. This

gives no idea of the incidence of injury to nerves or myocardium. Only two cases, with accompanying electrocardiograms, have been reported in which it was felt that there was cardiac injury; in one the vagal influence had not been ruled out by atropine and in the other the patient had received digitalis prior to the taking of the electrocardiogram; the tracing was normal three weeks later. There is no question that intoxication is manifested by rapid pulse, asthenia, vomiting and diarrhœa and that it often goes on to frank neuritis or palsy. As to how much actual myocardial injury is produced in patients who survive is still debatable. It has been suggested that tachycardia is due more to irritation of the vagus nerves than to the myocardial injury. The experiments on animals leave no doubt that emetine is a protoplasmic poison, while the nerve lesions are the result of degeneration of fibres in the motor roots and not actual neuritis. Clinically, emetine should be used at a point far below toxicity, leaving only a very small chance of reaction in the exceedingly hypersensitive individual. In many of the reported cases of intoxication and in our own there have often been warnings of intolerance which in retrospect are quite definite. In some cases the reaction appeared without any warning.

The probability of myocardial injury increases at the age of 60 years and beyond, so that one might expect to note some evidence of cardiac disturbance on giving emetine to older patients. There are data on twenty-five patients whose ages extend from 60 to 74 years, all of whom received from 0.26 gm. (4 grains) to 1.1 gm. (17 grains) in from two to four weeks' time (an average of 0.65 gm., or 10 grains). In two cases neuritis developed; in one the symptoms came on after 1.1 gm. (17 grains) of emetine had been given, and the patient suddenly recalled having recently received emetine elsewhere. Throughout the first three weeks during which neuritis was most marked, this patient's blood pressure held constantly at 175 to 180 mm. of mercury systolic and 90 to 94 mm. diastolic, with a pulse rate at 80 beats a minute. The second patient was not seen at the clinic after neuritis appeared, as it had followed a second course of 0.26 gm. (4 grains) of emetine administered by his local physician. Report was made only of weakness of the extremities. The remaining twenty-three patients showed no intolerance to the drug.

In the 554 cases at the clinic in which emetine was given (table I), there were eight in which there was generalized asthenia and weakness of the extremities to an extent that would justify classifying it as a neuritis or palsy. In eight other cases, exhaustion and general depletion were definite and possibly should likewise be considered as a mild palsy. The first eight patients

received emetine in doses of 1.1, 1.04, 0.65, 0.52, 0.91, 0.97, 0.65 and 0.78 gm. Six of the second eight patients received 0.78 gm., one received 0.75 gm., and one received 2.73 gm. In no case was there any particular reference to disturbance of the cardiovascular system. In six of these sixteen cases there were early warnings after the first course of from 0.24 to 0.39 gm. had been given, such as hives, increased diarrhoea, joint pain and weakness, but the administration of emetine was continued. In ten cases the symptoms appeared shortly after completion of the course of emetine. One must accept the entire sixteen, or 2.8 per cent of the 554 cases, as the incidence of emetine reaction; with our present average dose of 0.65 gm., however, it is noted that only three of the sixteen reactions occurred at this dose or less. Merely for contrast, as well as to emphasize the all important factor of individual tolerance, I have the record of three patients who received 8.3 gm. (125 grains), 8.7 gm. (134 grains) and 11.6 gm. (180 grains), respectively in a period of from eight to twelve months; in addition, many others have received two or three times the usual 0.78 gm. in three months' time. In none of these cases were there signs of intoxication. In two additional cases urticaria was prominent, and in still two others large ecchymotic areas, with induration, developed at the sites of injection. The last two might have been due to errors in technic or perhaps to a faulty product.

From these observations in 554 cases it hardly seems justifiable to discard emetine, although it should be re-emphasized that emetine in the total dose of 0.65 gm. in two weeks is employed only to control acute manifestations of the disease and to give the patient prompt relief but not with the idea of continuing with the drug to bring about a cure. With this in mind, exception will not be taken to my stating that three reactions to 0.65 gm. or less in 554 cases (0.54 per cent) is about the incidence of reaction or idiosyncrasy to emetine.

Organic arsenicals.—Arsphenamine, acetarsone and treparsol have been the arsenicals used at the clinic (table I). In the last two years we have had occasion to employ carbarsone, but in too few instances to justify any conclusions. From the studies of Reed, Anderson, David and Leake, carbarsone is shown to produce fewer reactions than either treparsol or acetarsone, although I have had reported to me two cases of toxic erythema and one case of neuritis. The slow elimination of carbarsone, as with acetarsone, suggested the possibility of an occasional neuritis. Arsphenamine has been put aside not so much from fear of it but rather because the expense and time element favoured orally administered drugs. Thirty-eight patients received arsphenamine, and with no untoward reactions.

Acetarsone was thoroughly tried and seemed to be the answer to the problem of an easy, inexpensive drug that would complement emetine, emetine being used for control of acute symptoms and acetarsone for eradication of the amebas. Deaths are recorded in several reports, but in the 232 cases in this study (and in many others in which acetarsone was prescribed) a death has not occurred. Toxic erythema has been noted, however, occasionally being severe enough to be considered as dermatitis exfoliativa; toxic erythema was encountered in thirteen (5.6 per cent) of the 232 cases in which patients received acetarsone (stovarsol). Three patients were quite ill for a week; the others were moderately sick and the symptoms abated in from forty-eight to seventy-two hours. Severe peripheral neuritis occurred in one case, recovery from which took almost a year. A second but milder case occurred, and the patient was well in from six to eight weeks. In both instances arsenic was present in the urine months after the administration of acetarsone had been stopped.

In view of these two cases of neuritis and thirteen of toxic erythema it was realized that the risk of treatment was considerable and that it was particularly dangerous to prescribe the drug unless the patient was under constant observation.

Flandin stated that the arsenic of treparsol was eliminated within two or three days after completion of a course of this drug. This suggested that the neuritic complication could be avoided and the immediate acute reactions perhaps lowered. Flandin's statement as to the rapidity of elimination was confirmed and, clinically, no cases of neuritis have occurred. Since 1925, 301 patients have received treparsol, and it was prescribed for others whose treatment was carried out elsewhere. There occurred eight, or 2.6 per cent, instances of toxic erythema in the 301 cases. One additional patient had nausea and vomiting after taking four tablets (1 gm.), and administration of the drug was discontinued rather than risk any chance of reaction. Four of these eight patients manifested erythema at the end of the first course (3 to 3.75 gm.), whereas four showed reactions during or toward the end of a second course of 3 gm. Symptoms of all subsided in from three to five days. While deaths from treparsol have been recorded, none have occurred in cases at the clinic.

While chiniofon ('yatren', 'anayodin') has been regarded with favour at the clinic and employed since 1926, it has not been the drug of first choice. Possibly

TABLE II
Results obtained with specific drugs

	'Cure'		Failure	
	Cases	Per cent	Cases	Per cent
Emetine ..	88	55	73	45
Ipecac ..	11	73	4	27
Arsphenamine	10	91	1	9
Acetarsone ..	112	85	19	15
Treparsol ..	34	89	4	11
Chiniofon ..	22	82	5	18

the earlier item of expense (when it was imported as 'yatren'), as well as the frequency with which it temporarily increased the diarrhoea, first led to the use of emetine, in conjunction with treparsol. Chiniofon is noted as being used in only thirty-seven of the 834 cases (table I). This gives a rather unfair picture, however, for most of these patients had received previous, and unsuccessful, treatment with emetine and arsenic. Aside from the rather frequent inconvenience of increased diarrhoea on the usual dose of 3 gm. daily, no untoward difficulties occurred. The two deaths that followed the intravenous administration of chiniofon in cases of actinomycosis are quoted constantly and indicate that the drug is not without some danger. However, the danger would seem minimal in the usual doses administered orally.

Vioform is another halogenated quinoline that has been used at the clinic. As it was available only during 1933 and 1934, it has been tried in only eighteen cases (table I). There were no difficulties and less irritation from its use than with chiniofon. As with carbarsone, we have had too little experience to offer any conclusions. Recently, a third compound of this group has been offered for trial, diiodohydroxyquinoline. In only one case has it been possible to follow up the patient, and in this case stool tests were negative three months after treatment.

The use of colonic irrigations of any of the foregoing medicaments has, unfortunately perhaps, not been tried. I have not been convinced that they added to the treatment, and no doubt there was an underlying prejudice against colonic irrigations.

As a matter of record, experiences with retention enemas of coal oil should be noted. In most instances there was no difficulty other than the attendant nuisance plus a persisting aroma of kerosene during treatment. A few patients would smell and taste kerosene in eructations of gas, which quite definitely was the result of reverse peristalsis. In one case a severe and rather dramatic reaction occurred. Immediately after receiving coal oil, the patient complained of a very tight feeling in the chest. The

[May, 1936]

respiration rate rose to 36 per minute and the temperature to 102°F. Coarse râles were heard in both lungs. The patient was very restless and apprehensive, and grave anxiety was held as to the outcome. The symptoms slowly subsided, however, and in twenty-four hours he had entirely recovered.

SECTION II: RESULTS OF TREATMENT

In the evaluation of results of treatment it is essential not only to have later and repeated examinations of stools but also to have information as to what types of amœbiasis are encountered in any particular report. The effectiveness of treatment in a group of cases of latent amœbiasis might be quite different from that in a similar number of cases presenting hepatic abscesses or acute dysentery.

In this review, 278 of the 834 patients (33 per cent) had evidence of active amœbiasis on admission, 424 (50 per cent) had intermittent diarrhoea associated with various abdominal complaints, some of which were and some of which were not improved by anti-amœbic treatment, and 132 (16 per cent) were considered as having latent amœbiasis. In the latent group were listed fifty-one patients with chronic ulcerative colitis, in all of whom colitis had persisted after anti-amœbic treatment. There is no doubt that the relative percentage of latent cases can be varied almost at will, depending on how routine the examination of the stool is. Since the stools of patients who come to the clinic are not all examined and, further, as this group of 834 cases consists merely of those in which data as to treatment are available, the foregoing percentages do not give a true ratio of the incidence of the various degrees of amœbic infection in the north temperate zone.

Of the total group of 834 cases, 523 afforded sufficient data to warrant tentative conclusions as to the results of treatment. It is realized that in many the ideal of repeated examinations over a prolonged period has not always been possible, yet I believe that the follow-up data have been sufficiently adequate to indicate what has transpired (table II). The word 'cure' is used in this paper to imply that not less than two examinations of stools were made on successive days following completion of treatment, while in most cases repeated examinations were made over a period of months to several years. In addition, clinical symptoms of amœbiasis no longer existed. 'Failure' implies that the parasite was identified in the stool after treatment was completed even though there were no clinical symptoms. In contrast to institutional patients, our patients had returned to their original environment, so that reinfection might have occurred; yet we have considered as failures any cases in which the parasites were found after conclusion of treatment.

Treatment with emetine consisted usually in giving an average dose of 0.78 gm. (12 grains) over a period of four weeks. In most cases a series of kerosene enemata were given during the month, and in a number of cases chaparro amargoso was administered orally. Hence whatever virtue there may have been in kerosene and chaparro, they did not enhance the value of emetine as a curative agent to any marked extent. The observation of emetine failing as a curative agent in 45 per cent of cases is in accord with that of many other observers. Ipecac, in the few cases in which it was used, shows a better result, but one that is still far from satisfactory; in addition there is marked

unpleasantness from its oral administration in 50 per cent or more of cases. Bismuth emetine iodide was frequently used to supplement other treatment, yet as a primary weapon of attack it seems to have been used in only two cases of which we have record, 'curing' the patient in one and failing in the other. Nausea and vomiting and diarrhoea occur in some cases, although they are less severe than with ipecac.

The primary results of treatment with the organic arsenicals is much better than with emetine or ipecac. Failure to obtain a cure, in addition to the occasional reaction, in only 9 to 15 per cent of cases, is most encouraging although still not at the desired goal.

Too few results are available on the efficacy of the oxygenated quinolines. It is not because of fear or prejudice but rather because there has been such a comfortable feeling with the emetine-arsenic regimen since before the quinolines were available that we have used them later more as 'shock troops'. In eight cases chiniofon (yatren) was used primarily, and in fourteen cases secondarily, for a total of twenty-two cures. Failure resulted in one case in which treatment was primary and in four cases in which it was secondary. This is not a just estimate of the drug's value, as the eighteen cases in which treatment was secondary indicate that a more stubborn infection existed. Likewise, too few results were available on the efficacy of carbarson and vioform. In only one case was vioform used alone; in this case active amœbic dysentery persisted in spite of the fact that emetine had been administered elsewhere to the point that peripheral neuritis had developed. Vioform failed to result in a cure. In two cases it was combined with treparsol and given but the results of treatment were unknown. Nine patients received carbarson, but data are available for only three of them. Used alone, carbarson failed to cure; in conjunction with chiniofon one patient was cured, and with emetine one failed.

The high percentage of failures with alkaloids and the much better results with the arsenicals naturally suggested the value of combining emetine and an arsenical, the former to be used only in sufficient dosage to control acute symptoms, thereby keeping well below even a minimal danger of poisoning, and the latter to be used in smaller doses and yet prove effective in eradicating the amœbas. The results noted in table III confirmed this opinion, for in 150 cases there were eighteen primary failures, or 12 per cent on treatment at the clinic. Ten of these patients were later cured, leaving eight regarding whom no further data were available. The final results were that treatment failed in 5.3 per cent and was successful in 94.7 per cent of the cases.

Results of treatment after original failure.—This is the group that naturally causes the most anxiety of all and serves as the stimulus to more effective treatment. As previously noted, the incidence of the more severe manifestations of amœbiasis is probably higher in the tropics, so that any reports from the north temperate zone may not be comparable to those originating in the Orient, in India or in Panama. In the 523 cases at the clinic 398 primary cures were obtained, but it is the 125 failures that are of the most concern (table IV). Striking improvement coincides with the wider use of the organic arsenicals. It also signifies that the profession has ceased to look to emetine as a curative agent but rather as a means of controlling the acute symptoms. Of the 125 patients whose original treatment failed, sixty were later cured; twelve persisted with the disease in spite of continued treatment, and for fifty-three no further data were available. It may be unfair to include all these fifty-three cases as final failures, just as it is rather optimistic to include all the remainder as true cures, but nevertheless sixty-five are listed as failures. But to consider these sixty-five as final and absolute failures is not justified, for as time goes on the majority of these present failures gradually become apparent cures, which observation has repeatedly been confirmed.

With present knowledge, the 'reclaiming of failures' lies in a systematic and conservative variation in the treatment. If failure has followed the use of emetine and treparsol, success is unlikely to follow their continued administration; likewise, the possibility of drug reaction increases. Two or three courses of chiniofon are prescribed (21 gm. a week, with a week's interval between courses). If amœbas persist, six weekly injections of arsphenamine or bismuth emetine iodide, with large doses of bismuth subcarbonate, are employed. In other words, varying the ammunition minimizes reactions to the drugs and seems more effective in finally

TABLE IV
Results of original and later treatment

obtaining a cure. As one reviews the sixty cases finally considered as cured, the barrage of arsphenamine, emetine, bismuth emetine iodide, chiniofon, carbarsone, acetarsone, treparsol, vioform and ipecac is indeed startling, and one asks what good any one drug is when such a variety is used. In any event, a cure was eventually obtained.

Of the twelve cases in which failure persisted even after further treatment, five occurred in 1920 when more emetine and ipecac were given. One patient later received one course (4 gm.) of acetarsone, but without avail; at present I would not consider that sufficiently varied and persistent treatment had been given. One patient had a course of six injections of arsphenamine after the course of emetine had failed. Another patient received 152 gm. of emetine (24 grains) on top of an original course of 0.78 gm. (12 grains). The other five patients received fairly intensive treatment with emetine, acetarsone, treparsol and chiniofon, but in spite of this the parasites were not eradicated. Although these five cases were still failures, yet of the sixty eventual cures in the original 125 failures these sixty had as much or more treatment, some for two to three years. Hence it is hoped that judicious and varied treatment with the present drugs will result successfully in almost all cases of amœbiasis encountered at the clinic.

The figure 91.1 per cent as representing cases in which an apparently final cure was obtained in the past decade will undoubtedly provoke criticism, and I realize that, if repeated examinations of the stools of these patients could be made over a period of months, the final result would be less. On the other hand, instituting the programme of variation in further treatment makes me optimistic enough to believe that the final outcome would yield as high or even a higher percentage. As one respects the potential dangers of the drugs that are employed, so the recognition of the amœba as a wily and stubborn enemy results in a more determined and judicious management. Again it must be stated that those manifestations of the disease are not encountered when one considers, ileostomy or appendicostomy, or colostomy for rectal stricture.

Among the more serious complications of the disease to be dealt with should be noted clinically recognizable injury to the liver, which occurred in twenty-two cases. In sixteen cases there was abscess formation, whereas

in six there were chills, fever, leukocytosis, and tenderness in the region of the liver, which certainly suggests hepatic involvement. As has been stated, one of the patients was practically moribund on admission and died of general peritonitis. Drainage of the abscess had been established and 0.39 gm. (6 grains) of emetine

TABLE V
Results of treatment on amœbic rectal ulceration

had been administered. Necropsy revealed that an abscess had ruptured into the peritoneal cavity.

In the remaining fifteen cases of known abscess aspiration or open drainage had been done, accompanied by anti-amœbic treatment. So far as we know, all these patients have been cured. Five of the six patients with hepatitis likewise have remained well, although the sixth, treated late in 1934, has written that she is still having some trouble.

With the exception of the patient who died and two others who were treated in 1920 and 1924, all patients received neoarsphenamine, acetarsone or treparsol in conjunction with emetine. In no case was there evidence of untoward reaction or of an increase in hepatic injury. In fact, in one case convalescence was prolonged and more complete recovery occurred only after treparsol was given; treparsol had been withheld for fear of injuring the liver. With even nineteen cases of hepatic injury it is not proper to state that the arsenicals are not dangerous, but in cautious and interrupted courses their administration has not only not caused harm but has proved beneficial.

Another aspect of the results of treatment of the more severe types of amœbiasis is seen in cases in which amœbic rectal ulceration could be demonstrated. Of 576 patients who were examined proctoscopically, 195 (33.8 per cent) had amœbic proctitis, 330 (57 per cent) were normal, and 51 (8.8 per cent) had idiopathic ulcerative colitis. The last were cases in which amœbas played only an incidental rôle and the colitis persisted after the amœbas had been eradicated. Several patients in the first group had some associated stricture, but only one had a marked tubular stricture. The last, a Nicaraguan, is one of a group of patients who received combined anti-amœbic treatment and local treatment of the rectum for more than three years; a cure was finally obtained and the patient had an adequately functioning rectum (table V).

PRESENT METHODS OF TREATMENT

If the patient has not received anti-amœbic treatment recently, he is given 0.065 gm. (1 grain) of Burroughs Wellcome & Co. emetine hydrochloride, subcutaneously, twice daily for three days. After an interval of a week, 0.043 gm. (two-thirds grain) of emetine is given twice daily for three more days. With the institution of the emetine, treparsol, 0.25 gm. (4 grains), is administered orally with each meal for four days. If there is no intolerance to arsenic, two more such courses are prescribed with intervals of ten days between the courses.

If the patient is quite ill, he is kept in bed for the first few days; if he is not particularly ill, hospitalization is not necessary. Obviously the diet may need to be bland and simple if there is much dysentery, but very rapidly, that is, within twenty-four to forty-eight hours, a full and generous diet is begun. In any depleting disease, adequate amounts of nourishing,

utilizable food are most essential. As recently demonstrated in experimental amœbiasis by the Tulane group (Faust, Kagy and others), the importance of a rich, high vitamin diet had a profound influence on the healing of amœbic ulceration. Hepatic involvement may subside, but if there is a large collection of broken down material, aspiration preferably, or occasionally open drainage, may be required.

If stool tests are positive following this regimen, three courses of chiniofon are prescribed: 3 gm. orally per day for a week and repeated for two more such courses, with a week's interval between courses. If diarrhoea is increased, the daily dose is decreased, thereby prolonging each course. Failure after this would indicate a course of one injection of arsphenamine weekly for six weeks, and 1 drachm (3.88 gm.) of bismuth subnitrate from three to six times daily during the period. As it was aptly expressed by Anderson and Reed, 'No one drug is known to-day to be completely effective..... and the therapeutic hazard should not exceed the disease hazard'. Hence there is need to vary the treatment in regard to the individual patient as well as to the type or degree of severity of the infection. With continued search for more effective and safer drugs, and with a better knowledge of the 'soil' of the patient, this present regimen will be simplified.

SUMMARY AND CONCLUSIONS

1. The use of 0.65 gm. (10 grains) of emetine hydrochloride subcutaneously in a month's time should involve a risk of reaction in less than 1 per cent of the cases.

2. The use of any of the present organic arsenicals is attended by some risk, but by observing the rule of interrupted courses as well as observation of the patient this risk is minimized.

3. In our experience at the clinic, acetarsone, treparsol and carbarsone have produced reactions. Clinically acetarsone produced the most and carbarsone the least.

4. The use of the arsenicals has not proved detrimental in the treatment of amœbic liver abscess.

Bacteriæmia and Oral Sepsis with Special Reference to the Ætiology of Subacute Endocarditis

By C. C. OKELL

and

S. D. ELLIOTT

(Abstracted from the *Lancet*, Vol. II, 19th October, 1935, p. 869)

THE INVESTIGATION

In searching for the ultimate source of the streptococci concerned in the production of subacute bacterial endocarditis, attention must inevitably be turned to the oral cavity. Practically all observers are agreed that the vast majority of endocarditis streptococci are of the salivary or *Streptococcus viridans* type. These abound in the mouth and its neighbourhood but are only found elsewhere in small numbers and under exceptional conditions; above all it is in conditions or oral sepsis such as pyorrhoea of the gums that this type of streptococcus is found in the greatest numbers.

BACTERIÆMIA FOLLOWING DENTAL EXTRACTIONS

Our first observations were made on the blood of patients undergoing extraction of teeth from both septic and clean mouths. It is admittedly not easy to classify the different varieties of oral sepsis. Gum infection and apical infection are rarely mutually exclusive conditions. We therefore divided the cases roughly into three groups, A, B, and C, shown in Table I.

The blood was examined for bacteria in 138 patients undergoing the operation of extraction of teeth. Ten cubic centimetres of blood were taken from the arm veins immediately before extraction, and another 10 c.cm. within five minutes after extraction. The blood was added to 1.2 c.cm. of 5 per cent sodium citrate saline. Both samples of blood were usually taken while the patient was under the influence of a general anæsthetic—nitrous oxide, Evipan (intravenous), or ether.

Blood culture technique.—Each sample of citrated blood was distributed as follows. Two 1 c.cm. quantities were plated with 10 c.cm. agar in order to obtain a count of the viable organisms should the culture be positive. The remaining 8 c.cm. of blood was divided into two equal parts, each of which was added to 20 c.cm. of 0.1 per cent sodium citrate broth. One blood-agar plate and one blood broth were then incubated aerobically at 37°C. for seven days; the remaining implants were incubated anaerobically at 37°C. for the same period. The aerobic cultures were inspected daily for the presence of bacterial growth; it was found that where the culture was positive, growth often first appeared on the third or fourth day of incubation.

It will be seen from Table I, that of 138 cases of dental extraction, 84 (60.9 per cent) showed a transient streptococcal bacteriæmia after operation, and that in cases considered to be of a severe type of oral sepsis (Group A), the positive streptococcal cultures reached as high a figure as 75 per cent. In all cases where streptococci were recovered the organisms were of the non-hæmolytic type.

In the majority of cases where the result was positive streptococci were recovered from the cultures grown under both aerobic and anaerobic cultivation, and in few instances were the organisms found in the aerobic or anaerobic cultures only. None of the streptococci recovered were obligatory anaerobes.

In general, it was found that the occurrence and degree of a bacteriæmia depended upon the severity of the gum disease and the amount of damage done at the operation. Of 10 cases where one tooth was extracted and where there was no noticeable gum disease, only one gave a positive streptococcal blood culture after operation; this was one of removal of an impacted wisdom tooth. In 6 cases where two carious teeth were removed from an otherwise normal mouth, 2 gave a positive streptococcal blood culture after operation, the number of colonies growing being less than 1 per c.cm. of blood.

In 10 cases where a positive culture was obtained directly after extraction, a third specimen of the blood was taken at a period varying from ten minutes to eight hours after operation. After these intervals the blood was always found to be sterile. The bacteriæmia following extraction is thus of very short duration.

Organisms other than streptococci found in the blood following extraction of teeth.—While in the majority of cases non-hæmolytic streptococci were isolated in pure culture, in 6 of the 138 cases already described (in which the blood was cultured before and after extraction of teeth), diphtheroid bacilli were found in the blood taken immediately after operation. In 3 of these cases the diphtheroid organisms were in pure culture while in the remaining 3 they were present in streptococci. In no case were these organisms present in the aerobic and anaerobic cultures at the same time; in 5 cases they grew aerobically and in 1 case anaerobically. Two of these cases showed no gum affection. In 2 further cases included in the series of 138, staphylococci were found in the blood taken after extraction. These organisms were of the *albus* type; once they grew in pure culture, while in the remaining case they were mixed with streptococci. In both instances they grew only in the aerobic cultures.

The isolation of staphylococci and diphtheroids, both found so commonly on the surface of the skin, is possibly but improbably to be ascribed to contamination.

TABLE I
Streptococcal bacteraemia following extraction of teeth in 138 cases

Case group	Type	Cases examined	Result of blood culture after extraction	STREPTOCOCCAL COLONY COUNTS. AVERAGE OF AEROBIC AND ANAEROBIC CULTURES				
				<1 c.c.	1 to 5 c.c.	6 to 10 c.c.	11 to 15 c.c.	>15 c.c.
A	Marked gum disease; multiple extraction.	40	30 + 10 — (75 % +)	5	17	2	2	4
B	Moderate gum disease; multiple extraction.	60	42 + 18 — (70 % +)	14	21	4	1	2
C	Without detectable gum disease; extraction of one or more teeth.	38	12 + 26 — (34 % +)	3	9	—	—	—

+ indicates that streptococci were present in the blood culture.

— indicates that no streptococci were present in the blood culture.

c.c. = per cubic centimetre.

PYREXIA FOLLOWING EXTRACTION OF TEETH

In 20 of the cases where teeth were extracted from patients with pyorrhœa, the temperature was taken at half-hourly intervals over a period of twelve hours following operation. In 14 of these patients some degree of pyrexia was found to occur four to nine hours after operation; the temperature usually rose sharply to a level between 99°F. and 102°F. and remained at this height for two to four hours, after which it fell abruptly to normal again. In 3 a third specimen of blood was taken during the pyrexial period, but in all it was found to be sterile although streptococci were found in the sample taken *immediately* after extraction of the teeth. In 3 of the cases where pyrexia was observed the blood culture immediately following extraction was negative, while in 3 where there was no rise in temperature a bacteraemia immediately followed operation. Three further cases showed neither a positive blood culture nor pyrexia following operation.

These observations cannot be said to show any clear relationship between post-operative bacteraemia and pyrexia. The time relationship, however, between the trauma, the bacteraemia, and the pyrexia was very similar to that observed by Barrington and Wright in connection with catheter fever, and possibly bears the same interpretation as that suggested by these observers—*viz.*, that the pyrexia follows the bacteraemia at an interval similar to that which elapses between the injection of bacteria or protein into the circulation and the subsequent pyrexia (non-specific shock).

BACTERIÆMIA IN RELATION TO DENTAL SEPSIS

The most unexpected of our findings was that in 12 cases streptococci were isolated from a specimen of blood taken *before* operation. Of these, 9 were amongst the 100 cases of pyorrhœa referred to in Table I (Groups A and B), streptococci being found both before and after extraction of teeth. The remaining 3 cases were from an additional 10 cases of pyorrhœa in which only one examination of the blood was made, that being before extraction. Thus, among 110 cases of pyorrhœal disease, 12 (10.9 per cent) were found to have a streptococcal bacteraemia at the time of examination, irrespective of operative procedures. In 5 cases there was a definite increase in the colony-count of the specimen taken immediately after extraction of teeth, in 1 case there was a diminution in numbers, and in 3 cases less than one colony grew per c.cm. of blood, both before and after operation, so that no change in degree of the bacteraemia could be detected.

The blood of 2 of the patients was examined on two occasions, the tests being separated by an interval of a week. In both patients streptococci were found to

be present in the blood on the second but not on the first occasion. In 3 of the 9 cases where streptococci were found in the blood both before and immediately after extraction, the blood was examined again one to six hours after operation but was then always found to be sterile. It appears, then, that the inflammatory reaction following extraction closes down the field of absorption of organisms.

Organisms other than streptococci found in the blood before extraction of teeth.—In 6 of the 110 cases of pyorrhœal disease mentioned above, staphylococci were isolated in pure culture from the blood before dental extraction. All six were of a severe type of gum disease. Two of the six staphylococci were hæmolytic for horse blood, one being of the aureus type.

DISCUSSION

From time to time cases of subacute bacterial endocarditis are met with which follow the extraction of one or more teeth. The foregoing observations indicate the source and mode of infection in such cases. The transient bacteraemia following operative trauma is analogous with that described by Barrington and Wright in catheter fever where *B. coli* was the usual organism isolated from the blood.

More interesting is the observation that in persons with severely septic mouths non-hæmolytic streptococci (mostly of the *viridans* type) may enter the blood stream in the absence of any obvious trauma. Owing to difficulties of access to patients our own observations on this point are very incomplete. We have been unable to ascertain whether the condition of 'leak' into the blood stream in the positive cases is continuous, intermittent, or merely a fortuitous single occurrence. Nor have we yet determined whether minor degrees of trauma, such as brushing the gums or chewing, have any effect on the occurrence of the bacteraemia. There are, however, certain implications from which it is difficult to escape. From the nature of the technique it is likely that many cases in which streptococci enter the blood stream were missed. The efficient mechanism which exists for clearing the blood stream of organisms of low virulence no doubt only allows a 'leak' of organisms into the circulation to be detectable in blood from an arm vein when the 'leak' exceeds a certain magnitude or the organisms are abnormally resistant to phagocytic clearing. The small percentage of cases in which this non-traumatic 'leak' was observed probably gives an under-estimate of the risk of streptococci entering the blood of persons with severely septic gums. The bacteraemia observed under these conditions is obviously not an infection of the blood in the ordinary sense but is rather a 'leak' of relatively

non-pathogenic organisms into the general circulation followed by their rapid removal by the phagocytic action of the body. It is generally admitted that damage or malformation of the valves is a frequent if not a necessary predisposing cause of subacute bacterial endocarditis. It is easy to imagine that the 'leak' which is of little account in the normal person might determine the infection of diseased or malformed valves. At least the direct observation of such an invasion of blood as we have described provides a tentative explanation of how streptococci reach the heart valves in cases of subacute bacterial endocarditis and one in agreement with views which are widely held on theoretical grounds.

SUMMARY

(1) Within a few moments after the extraction of teeth from obviously septic mouths, a transient streptococcal bacteraemia lasting a few minutes may be observed in 75 per cent of cases. (2) Even in patients with mouths showing no obvious gum disease, extraction of teeth is followed by a transient streptococcal bacteraemia in 34 per cent of cases. (3) Of 110 persons with septic mouths 10.9 per cent were found to have a streptococcal bacteraemia irrespective of any operative interference. These observations were based on the examination of the blood on a single occasion. (4) The organisms isolated from the blood in the majority of cases were streptococci of the *viridans* type which were culturally and serologically similar to strains derived from the mouth. (5) The possible bearings of these observations on the aetiology of subacute bacterial endocarditis are briefly discussed.

Trichomatous Conjunctivitis: Its Surgery and Pathology

By A. F. MacCALLAN, C.B.E., M.D. (Camb.),
F.R.C.S. (Eng.)

(Abstract taken from the *Lancet*, 25th January, 1936, p. 215, of a Hunterian Lecture delivered at the Royal College of Surgeons of England on 17th January, 1936)

DURING the last thirty years trachoma has become a comparatively rare disease in London. Ophthalmologists can realize with difficulty that the stigmata of the disease are borne by as many as half the inhabitants of the globe. For it is practically universal among the Mongolian and Semitic races, and among the Red Indian tribes; it is also widely spread among the Caucasians of India, and among the Malaysians. Nevertheless, our knowledge of the aetiology of trachoma is incomplete; the clinical diagnosis may be impossible in the absence of bulky and expensive apparatus, and no aids are to be obtained by means of chemical or microscopical tests; while the treatment has not improved during the last thirty years.

PATHOLOGICAL ANATOMY

The response to attack by the virus of trachoma is a generalized flooding of the subepithelial tissue of the conjunctiva with lymphocytic cells. Typically, there are in addition special aggregations of these cells, which have been called follicles; however, in some cases no such follicles are to be differentiated from the general exudate of lymphocytes (Mikhail). The follicles, when present, differ in no way from similar aggregations of cells which appear in the condition known as follicular conjunctivitis. The conjunctival epithelium first proliferates, and then becomes villous; or it ulcerates and becomes replaced by scar-tissue epithelium.

The numerous underlying sebaceous or meibomian glands are at first affected by simple blockage of ducts and dilatation, the result of pressure by the cellular infiltration. Later the ducts become strangulated by the developing connective tissue, which begins to take the place of the lymphocytic exudate. The result is the appearance on the surface of the conjunctiva of

numerous bleb-like excrescences, which burst on pressure, giving vent to gelatinous matter, the retained secretion of the sebaceous glands, with numerous cells. These bleb-like excrescences by all trachomatologists up to the present time have been looked upon as the follicles, described above, which have become dilated. There is no evidence that such dilatation occurs, nor has anyone ever observed such a phenomenon to develop. It would be impossible for such a metamorphosis of the follicles to occur. Mikhail also has observed the dilatations of the ducts of the meibomian glands, but has not connected them with the bleb-like excrescences of the second stage of trachoma.

The whole process, for the description of which I am indebted to Pulvertaft, is a chronic progressive inflammatory change, almost certainly due to a secondary infection of the subepithelial tissues, following a primary epithelial lesion. The difference between other forms of conjunctivitis and trachoma is that the effect of the virus is much more lasting in trachoma, leading to this enormous subepithelial exudate, which penetrates to the tarsus, and via the fornix conjunctiva to the upper corneal limbus. The natural end of this severe exudate is its transformation into cicatricial tissue, thereby differentiating trachoma from other forms of conjunctivitis. The involvement of the tarsus in the cellular exudate, and the subsequent cicatrization which occurs, leads to thickening of this boat-shaped structure, and so to entropion. The trichiasis which accompanies the entropion is due to the development of supernumerary lashes by offshoots from existing hair follicles. This new development is caused by the hyperaemic condition of the lid margin which always occurs in serious cases of trachoma.

The hypertrophy of the superficial conjunctival epithelium leads to the appearance of numerous polygonal areas, which form a papillary hypertrophy. This is the result of irritation and is present in all forms of long-continued inflammation of the conjunctiva.

Pannus

The term pannus was originally applied to the cloth-like opacity which the cornea of an inveterate case of trachoma exhibited. Completely ignorant of the pathology of the disease the surgeons of a former day used to attempt its removal. We now understand the term pannus to apply to an infiltration of the clear cornea by a cellular exudate, which is accompanied by the vascularization of a previously avascular tissue. This may be observable only by optical magnification, or may be obvious to the naked eye. Following the primary epithelial lesion of the conjunctiva by the trachoma virus, whatever its nature may be, there is an infection of the subepithelial tissues to which response is made by a widespread inflammatory exudation. This spreads from the site of origin, near the retrotarsal fold, to the fornix, travelling beneath the epithelium, and from the fornix proceeds to the upper part of the limbus of the cornea. In this area pannus appears, which in early trachoma is the only pathognomonic sign of the disease.

Mikhail has made it quite clear that the changes at the upper corneal limbus occur in this way, and that the limbus does not become infected from the trachomatous conjunctiva of the upper lid by contact.

The cellular invasion of the cornea has spread in the subepithelial tissue from the fornix. An increased vascularity is the response to this irritation. From the convexity of the end capillary loops of the cornea new vessels are developed which run centripetally towards the centre of the cornea with few anastomoses.

The cellular invasion appears first as an indefinite grey infiltration at the limbus, which often becomes concentrated into a number of tiny grey elevations. These are about 0.2 or 0.4 mm. in diameter. They are separated from one another by the new vascular channels just described. The cellular infiltration accompanied by new vessels inserts itself between the corneal epithelium and Bowman's membrane. In severe cases

Bowman's membrane may become partially destroyed, when the infiltration will penetrate between the layers of the corneal stroma. Marked opacity is thus produced, which becomes permanent on conversion of the inflammatory exudate into cicatricial tissue. The folly of an attempt 'to cure pannus' by peritomy or other ill-conceived measures, therefore, becomes apparent.

Four main points are of importance in our conception of the disease and in its diagnosis.

(1) The primary epithelial lesion caused by the virus results in an inflammatory reaction in the subepithelial tissue, exhibited by a lymphocytic infiltration. The lymphocytes may be aggregated into follicles, but this is not always the case. When such follicles are present they cannot be distinguished pathologically from similar aggregations of cells which occur in follicular conjunctivitis.

(2) This lymphocytic invasion of the subepithelial tissue spreads from its area of inception in the tarsal conjunctiva to the upper fornix, and thence in the bulbar conjunctiva to the corneal limbus, where changes occur peculiar to trachoma.

(3) The bleb-like excrescences, which exude a gelatinous material when ruptured, have no relation to the so-called trachoma follicles of an earlier stage of the disease.

(4) The lymphocytic invasion of the subepithelial tissue penetrates the tarsus, and finally is resolved into connective tissue. Hence result the deformities of the lids which occur in no other form of conjunctivitis.

The last three points differentiate trachoma from any other form of conjunctivitis.

CLINICAL MANIFESTATIONS

In heavily trachomatized countries such as Tunisia, Egypt, and Palestine, the disease is frequently discovered during the course of, or during convalescence from, an attack of acute bacterial conjunctivitis. But, as Charles Nicolle has said, the acute conjunctivitis is the occasion of the diagnosis, and not the occasion of the disease. The majority of the inhabitants of these countries become infected during the first two years of life. Born of trachomatous mothers, and suckled for nearly two years, it can be only by a miracle that infection will be avoided.

Typically the disease begins imperceptibly. Atypically and rarely it begins with acute symptoms such as pain, lachrymation, and photophobia, in the absence of bacterial infection. But these acute symptoms appear when the disease has already developed, as the result of roughnesses of the upper palpebral conjunctiva, which cause irritation of the corneal nerves. So this is an exacerbation of an existing condition, and not an acute onset. We can now enunciate a definition of trachoma.

Trachoma is a specific contagious disease of the conjunctiva in man. It is chronic in nature. It is characterized by a subepithelial infiltration of the conjunctiva by a cellular exudate, which spreads to the tarsus and to the cornea. It is followed by cicatricial changes in the affected tissues.

Four stages

The disease is divided into four stages, according to the comparative prominence of subepithelial lymphoid infiltration, bleb-like excrescences which burst on pressure, papillary hypertrophy, and connective tissue formation.

(i) After an incubation period of from 4 to 10 days, the first stage makes its appearance by a subepithelial infiltration. This infiltration is usually, but not always, concentrated into tiny greyish islets, the so-called follicles; these form slight roughnesses, and first appear at the extremities of the tarsal conjunctiva at its upper border.

The virulence of the trachoma virus is such that the subepithelial infiltration rapidly extends to the conjunctival fornix, and from thence to the upper corneal

limbus. Pannus is present as soon as the condition can be diagnosed; in fact the diagnosis rests on detecting pannus with the corneal microscope.

(ii) The second stage has been divided into sub-groups for application to different clinical appearances which are common in the East. For present purposes only one need be mentioned. Here there are numerous bleb-like excrescences, which rupture on pressure, with emission of gelatinous material. These are dilated ducts of sebaceous or meibomian glands. They have no relation to the tiny follicles of the first stage.

(iii) The third stage shows the resolution of the inflammatory infiltration commencing and its replacement by scar tissue. Typically there are islands of inflamed conjunctiva surrounded by a cicatricial network. There is always some thickening of the tarsus by inflammatory products, often leading to entropion.

(iv) In the fourth stage all inflammatory changes have come to an end. The tarsus is covered by scar-tissue epithelium and there is more or less cicatricial change in the thin subepithelial tissue and in the tarsus.

Ætiology

Now that the interest in the organism discovered by Noguchi, and reported by him as the causative agent of trachoma, has entirely evaporated, we are left with a theory that the disease is caused by a virus, and has some relation with certain inclusions in epithelial cells. These inclusions were first described by Prowaczek and Halberstaedter, who made experimental investigations in Java. They are not peculiar to trachoma, but are found in other ocular diseases, such as non-gonococcal ophthalmia neonatorum, follicular conjunctivitis, and swimming-bath conjunctivitis. They are indistinguishable from those found in certain known virus diseases, such as vaccinia, fowl-pox, varicella, herpes, and psittacosis.

PRINCIPLES OF TREATMENT

It must be understood that the disease is a local one, confined to the eyelids and the cornea; that it confers no immunity until the normal epithelium has been replaced by scar-tissue epithelium; and that it produces no recognizable blood reactions. The result of the action of the trachoma virus is an infiltration of the conjunctiva and cornea with lymphocytic cells. This is a manifestation of the defensive mechanism of the body tissues and fluids; the question immediately arises as to the utility of attempting to destroy this phenomenon, for no chemical or biological agent has been shown to have any neutralizing effect on the activity of the disease.

It is in the first stage of the disease that these doubts assail our minds. In the second stage, with its bleb-like excrescences, it is clearly necessary, by mechanical means, to get rid of the retained secretion in the blocked ducts of the meibomian glands. In the third stage the application of irritants, such as copper sulphate, is supposed to favour the deposition of fibrous tissue, at the expense of the lymphocytic infiltration.

A distinction must be drawn between 'mass' and 'individual' treatment.

Mass treatment at a clinic, where the actual manipulation of the lids is entrusted to nurses, is unsatisfactory; it is doubtful if it is preferable to the daily instillation of antiseptic or astringent drops by the patient himself. Individual daily treatment by an experienced ophthalmologist gives a better result, with the minimum amount of cicatrization.

The principal sequelæ of trachoma are trichiasis and trichiasis-entropion. Some of the operations, which have been proposed to rectify the condition, should never be performed: such as Burrow's operation, which is usually followed by a recurrence; Gaillard's sutures, which depend on suppuration for their effect; and Flarer's operation, or scalping of the lid margin, which results in permanent misery for the patient; for the lash-less lids roll in, and become macerated by the

conjunctival secretion. The principles which should govern operations are:

(1) The epilation of lashes should be strictly forbidden.

(2) The eyelid should not be fixed in a clamp for operative purposes, but should be stretched on a metal shoe-horn.

(3) No skin should be removed from the lid.

The operations to be recommended are Streatfield's operation in which horizontal wedge-shaped strip of the tarsus is removed from its anterior surface, and Van Millingen's operation in which a mucous membrane graft is inserted in the free border of the lid posterior to the lashes.

PROPHYLAXIS

In Egypt, Tunisia, Syria, and India the employment of native nurses for European children entails severe risk of trachomatous infection. In the annual report of the Public Health Commissioner with the Government of India for 1933, it is stated that at King George's Royal Indian Military School, Ajmer, the trachomatous boys have not been segregated from their healthy comrades during the last years on the advice of the Poona ophthalmologist. The report goes on to state that no new cases of trachoma have been reported as the result of this measure. This sounds satisfactory; however, as there is no information as to whether the trachomatous boys had regular daily treatment applied to their eyelids, for the purpose of preventing infection, it is not convincing. To be so it would be necessary to have a record of the corneal microscopy of all supposed healthy boys.

If at a private school or at the house of a public school, where a son of mine was attending as a boarder, it came to my knowledge that a boy with active trachoma was admitted, I should at once remove my son. I have seen a boy infected with trachoma at a day school for English boys in one of the Crown colonies. I have also seen the serjeant-major of a territorial regiment become infected after a period of duty with an Indian regiment.

Calcium Cyanide Dust in Ship Fumigation

By C. L. WILLIAMS

(From *Public Health Reports*, Vol. LI, 7th February, 1936, p. 139)

AMONG the procedures introduced of late years as improvements in ship fumigation, one of the most important has been the direct injection of fumigating gases into rat harbourages as a preliminary step to general gassing of the whole ship. By this procedure the fumigant is directly introduced into the spaces where the rats seek protection instead of depending on slow, haphazard, and unreliable penetration and diffusion.

It would appear that an improvement of this type would be generally taken up at once, but such has not been the case. As a matter of fact, it can hardly be said to have been taken up at all, the use of such procedure in the United States at the present time being restricted to two or three quarantine stations.

The reason for this is really not far to seek. Quarantine officers in general appear not to be prone to adopt readily procedures that represent additional work and hazard; obviously, direct injection of rat harbourages is of this type. However, all quarantine officers cannot be held at fault; at some stations the apparatus and specially trained personnel required cannot be reasonably maintained, and it must be admitted that in utilizing liquid HCN as an injection material the method is somewhat laborious and adds distinct hazards.

Attempting to view human nature as it is and not as he would like it to be, the writer has endeavoured during the past 2 years to develop simplified and safer methods of directly injecting hydrocyanic acid gas into

rat harbourages, with the hope that thereby a procedure might be developed so simple and relatively safe that its adoption at all major quarantine stations could reasonably be insisted upon. The use of calcium cyanide dust is offered as such a method.

METHOD OF PROCEDURE

As a matter of fact, direct injection of rat harbourages with calcium cyanide dust is simplicity itself. The dust is taken from a tightly covered can, in which it is marketed, by dipping it up with a large spoon or small cup. It is poured into the container of a foot-pump type of duster, this container then being screwed in place. The rubber hose extending from the duster (fitted with a nozzle if desired) is inserted into small openings into harbourages by a fumigator while another operates the pump, usually 2 to 4 strokes in each harbourage being sufficient. If the enclosed spaces to be treated are few or of limited extent, the whole operation might be carried on, even in the hold of a ship, without the wearing of gas masks by the fumigators. If, however, many harbourages are to be treated or they are extensive, gas-mask protection is necessary.

CALCIUM CYANIDE

The material used, calcium cyanide [the formula of which is $\text{Ca}(\text{CN})_2$], is manufactured in this country in the process of manufacturing cyanamide for use as a fertilizer. So far as the writer is aware, it is at present manufactured in the United States only by the American Cyanamid and Chemical Corporation, under the trade name Cyanogas. It is also manufactured in Germany, the German product being sold in this country under the trade name Calcyanide.

Cyanogas is obtainable in flakes, granules, or as a dust, the latter being quite fine, most of the particles passing a 200-mesh screen. Calcyanide is at present obtainable only as a fine dust, although it is available abroad in the form of briquets, which are usually broken into a dust for use. Cyanogas is blue in colour, while Calcyanide is a light brown. Cyanogas contains from 40 to 50 per cent calcium cyanide, while Calcyanide contains from 80 to 85 per cent calcium cyanide. This is an important point to remember, since in interchanging these materials the Calcyanide must be used in approximately half the amounts of Cyanogas. For use in the foot-pump duster, the form of Cyanogas to be specified is the 'A' dust.

The action of calcium cyanide is based upon the fact that it takes up moisture from the air to form hydrocyanic acid and calcium hydroxide; the former is liberated as a gas. The thinner the layer exposed to the air, the more rapid is the reaction. When a duster is used, the dust is blown out as a cloud and the reaction with the moisture of the air is almost immediate, continuing up to the point where the moisture present is exhausted. The limiting point is not reached when calcium cyanide is used, as described herein, for ship fumigation. The amount of HCN produced is approximately one-half the weight of the calcium cyanide entering into the reaction. Therefore, when Cyanogas is used, the HCN produced will be between one-fifth and one-fourth of the weight of the raw material. When Calcyanide is used, it will be approximately two-fifths of the weight of the raw material.

The reaction between water and calcium cyanide is reversible, that is, the calcium hydroxide in the presence of hydrocyanic acid takes up this material to produce calcium cyanide and water. This is of some importance where large amounts of calcium cyanide are used and it is spread in relatively thick layers. Where the material is dusted widely in relatively small amounts, however, the amount of HCN that will be retained in the residue is not likely to be dangerous.

FOOT-PUMP DUSTER

The foot-pump duster that has been used in experiments with Cyanogas and Calcyanide is one supplied

commercially by the American Cyanamid and Chemical Corporation and is built for the purpose of dusting their Cyanogas 'A' dust. This duster operates equally well, however, with Calceyanide. The device consists of an air pump attached to a stirrup at the bottom; one foot is placed in the stirrup to hold the apparatus steady while pumping. The stirrup is tall enough to accommodate a one pint glass mason jar or a similar jar made of aluminium, which is preferable. The jar screws into a fitting on the bottom of the pump. Air from the pump passes into the jar through a check valve and out of the jar through a delivery hose. On the down stroke, about one-fifth cubic foot of air is blown at high velocity through a small opening into the container, where it stirs up the dust and carries a portion of it out through the delivery tube. Approximately 1/12th ounce of the dust is delivered at each stroke.*

DOSAGE

The vast majority of rat harbourages are either of small capacity or are subdivided into small spaces. When subdivided, of course, each subdivision must be separately injected. As a rule, a harbourage or a subdivision will not be of more than 10 cubic feet capacity, and often is of not more than 2 or 3 cubic feet capacity. Since the foot-pump duster delivers about 1/12th ounce of the dust per stroke, the Cyanogas 'A' dust delivered by a single stroke will, in a pipe casing of, say, 4 cubic feet capacity, produce a theoretical HCN concentration of about 3½ ounces per 1,000 cubic feet. If Calceyanide is used, the concentration will be about 7½ ounces per 1,000 cubic feet. Two strokes, of course, will produce approximately twice these concentrations in such a space.

In experimental work with pipe casings, it was found by titration of the HCN present that the theoretical figures cited were not actually attained, probably because of absorption of gas and leakage. Furthermore, in considering this problem one must bear in mind that, in practice, leakage will be considerable and that the concentration will rapidly fall unless the harbourage injected is of very tight construction.

* Recently this duster has been improved by attaching a by-pass valve, permitting air alone to be pumped through the hose, so that a charge of dust may thereby be widely distributed. A duster with a 2-quart dust jar is obtainable.

In actual practice on ships, a number of different dosages were utilized; but it was found that, for the majority of harbourages not in excess of 10 cubic feet capacity, four strokes of the pump when Cyanogas was used, or two strokes of the pump when Calceyanide was used, gave excellent results in rat destruction.

SAFETY

In distributing calcium cyanide dust with a foot-pump duster as described, the hazard to the operators is low. This is due principally to the fact that while high concentrations of HCN are produced in the restricted harbourages, the actual amounts of dust liberated are so small that concentrations in the open ship's hold remain quite low. So far as the apparatus is concerned, the only hazard of any material importance is the possibility that the dust container may become loosened and drop off just as the pump is operated. This would cause a blast of dust to fly up in the face of the operator. Danger from such an accident can be entirely obviated if the operator wears a gas mask. In actual practice during experiments to test this material, no such accident has occurred, and no fatalities from such accidents are reported in the literature despite the fact that this type of dust pump is extensively used in destroying burrowing rodents on farms throughout the United States.

Because the absolute amounts of dust injected into harbourages are small, the dangers from gas being held in these harbourages and later escaping into the ships' holds after they have been cleared is practically nil. This is apparent when one considers that the harbourage is of only a few cubic feet capacity while the hold is from 30,000 to 100,000 cubic feet in capacity. An amount that may produce a high concentration inside a 4-cubic foot pipe casing becomes hardly more than a smell when liberated into the open hold.

FUMIGATING HOLDS

Calcium cyanide dust may also be readily utilized to fumigate ships' holds by blowing it into them with compressed air or some type of centrifugal blower. A vacuum cleaner with the bag replaced by a delivery hose does very well; it can be utilized also in the superstructure, but there presents the disadvantage that the fine dust, universally distributed, presents a subsequent cleaning problem.

The Calceyanide Co. also offers an apparatus wherein the HCN is extracted by air in a large bag and the gas-laden air, free from dust, is delivered through a hose, which obviates the cleaning problem.

Reviews

PHARMACOPŒIA AND GUIDE. Art Press, Calcutta. 1936. Pp. xi plus 153. Price, Rs. 2-8

THIS small book is an opportune production because, as far as we are aware, it is the first hospital pharmacopœia to be published from a hospital dealing specially with tropical diseases.

The first section is devoted to standard formulæ and there is nothing specially original in this section as it is mainly composed of the usual prescriptions found in hospital pharmacopœias, in fact many of them have been copied from those of well known London hospitals, but a few will not be found in the latter. There is an important departure from the normal, however, in that all prescriptions are written in full and in plain English, a valuable point for persons not grounded in Latin. This section is followed by a posological table of pharmacopœial drugs and tables of weights and measures. This portion occupies fifty-five pages, almost exactly one-third of the book.

It is in the latter two-thirds that the true value and unusual character of the book, as a hospital pharmacopœia, will be found, for here are given summaries of

diagnosis and treatment of all the tropical diseases one encounters in India, and this portion is of great practical value as each section has been compiled by the specialist workers of the Calcutta School of Tropical Medicine and it embodies all the methods they have found by long experience to be of greatest value.

In addition to this there are guides to laboratory procedure in carrying out the most important biochemical tests in use, and tables of normals, making it quite useful as an emergency laboratory handbook. There are also long lists of the food value of the ordinary articles of diet with a special table dealing with the fruits and vegetables common in India, and which play such an important part in the diet of the people of this country.

It is impossible in a brief review to enumerate all the good points in a book of this nature, but it is felt enough has been said to indicate its value.

This book is of pocket size being printed on thin paper of good quality and with a soft cover, and it is felt that it will meet a ready demand, first in India and the East where the diseases dealt with exist, but

it would also be of great use in any tropical country, and even a practitioner in England might find it a help if suddenly faced with a tropical complaint and without any textbooks at hand.

The price Rs. 2-8 is very reasonable and remarkably good value, and the Calcutta School of Tropical Medicine and the publishers are to be congratulated on its production.

REGENERATION IN MAN.—By M. A. Ansari. 1935. D. B. Taraporevala (Hornby Road, Fort), Bombay. Pp. xx plus 208. Illustrated. Price, Rs. 8. Obtainable from Messrs. Kegan Paul Trench Trubner and Company, Limited, London

The first portion of this book is devoted to a survey of the early work on the subject of regeneration beginning with the observation of Brown-Sequard and tracing the development of the technique up to the work of Voronoff and Steinach.

In the latter part the author describes the different methods employed and gives illustrative cases from among the large number he has operated upon.

The book is a good summary of our present knowledge on the subject of regeneration in man, and is clearly written in simple language. Typographical errors are remarkably few, the book is well printed, the illustrations excellently reproduced. It is one of the best examples of the printer's art we have encountered which has come from an Indian publishing house.

CHILD PSYCHIATRY.—By Leo Kanner, M.D. 1935. Baillière, Tindall and Cox, London. Pp. xviii plus 527. Price, 27s.

It is hardly a matter for surprise that this remarkable book is an end-product of American research in view of the prominence that pædiatrics has attained in the United States. This is the first textbook on child psychiatry to be published in the English language, hence the English-speaking world should be grateful to the Josiah Macy Jr. Foundation, as well as to the Rockefeller Foundation for providing the funds for the research upon which this book is founded. Dr. Kanner's outlook on mental disorders in children is based on the teaching of the eminent American psychiatrist, Dr. Adolf Meyer, which is that of objective psychobiology. As Dr. Kanner observes, of late years, a compromise has been attempted between the dualistic principle of interaction between body and soul and the monistic tenets of a dominance or sole existence of either 'mind' alone or 'matter' alone. In other words, the concept known as *psychophysical parallelism*, which assumes a coincident but otherwise not inter-dependent 'parallel' running together of a mental and a physical aspect. With this attitude as a background, child psychology becomes an objective and concrete study of the mentally integrated individual during the natural progress of maturation. Dr. Kanner explains the nature of the psychobiological approach in the following words: 'A child is brought to the physician's attention with a complaint. This may consist of a lesion of the skin, an exanthematous condition, otitis media, whooping cough, or constant blinking. It will, in every case, become necessary to obtain a careful history of the onset of the difficulty, the mode and circumstances of its first appearance, its development up to the time of the consultation, and the therapeutic attempts already undertaken.... The complaint may be of such a nature that it does not involve the child's personality in the least, beyond the desire on the part of the patient, or the family, or both, to have it corrected: a furuncle, a sprained ankle, uncomplicated varicella, the transient results of casual over-eating.... There is a vast range between these disorders and such complaints in which the patient's personality is very obviously and conspicuously in the foreground, as in temper tantrums, hypochondriasis, obsessive thinking, persistent day-dreaming, masturbation, excessive restlessness, truancy or stealing. In order to do equal justice to these, and similar, sometimes not so strikingly personality-determined difficulties, one would have to

study carefully the child's personality'. In the first nine chapters, Dr. Kanner deals with the problems of examination and diagnosis, beginning with a chapter devoted to the general consideration of the examination of children. Thereon follow eight chapters which deal with special points of the examination problem. These special points comprise, the complaint factor, the age factor, the somatic factor, the intelligence factor, the emotional factor, the sex factor, the constitutional factor and the environmental factor. Each point is admirably illustrated by copious citations from actual case histories. The author then passes on to the consideration of the principle and aims of psychiatric treatment. Under this heading, he includes work with the child, work with the family and work with the community. The remainder of the book is divided into three main sections: (1) personality difficulties forming essential features or sequels of physical illness; (2) personality difficulties expressing themselves in the form of involuntary part-dysfunctions; (3) personality difficulties expressing themselves clearly as whole-dysfunctions of the individual. The concluding chapter deals with the subject of suicide among children. Indian readers of this book, unacquainted with the conditions of the poor in Europe and the United States, will experience feelings of surprise amounting to consternation, when they learn of the amount of ignorance, cruelty, and gross superstition which still persists among races which pride themselves on their 'superiority'. Indeed, those readers who are acquainted with America and Europe, will be harrowed by the revelations of child life to be found in Dr. Kanner's clinical histories. From what Dr. Kanner has written about the facilities for the care of children, Indian readers may draw some comfort from the reflection that even in so wealthy and advanced a country as the United States, financial inadequacy, political meddling, the indifference and ignorance of legislators, the lack of progressivism and vision on the part of law courts in America, present endless difficulties and sources of obstruction in regard to the promotion of child welfare. Persons disgusted with the 'mumbo-jumbo' which passes for child welfare in this country will smile at the story of the wise judge who caused a girl of fifteen who had given birth to a child to be married to the baby's (putative) father. The couple lived together for exactly twenty-five days.

O. B-H.

HÆMOCHROMATOSIS.—By J. H. Sheldon, M.D. (Lond.), F.R.C.P. (Lond.). 1935. Oxford University Press, London. (Humphrey Milford.) Pp. xii plus 382, with 40 illustrations and 2 charts. Price, 25s.

PROFESSOR SHELDON'S interesting and illuminative monograph dealing with the various aspects of the hitherto unsolved problems of hæmochromatosis will no doubt be recognized as a classical work on the subject. The disease undoubtedly is a rare one and the present name was given by von Recklinghausen to a condition in which the organs and the tissues throughout the body are abundantly infiltrated with two pigments, one iron-containing identical with hæmosiderin, and the other appears to be the same as hæmofuscin.

The mysterious nature of the disease, which has eluded the vigilance of many workers in different parts of the world since the time of Trousseau (who appears to have first described a case in 1865) will be evident by the variety of names given to the disease by different workers in different parts of the world.

Though a very large volume of work has been done, the ætiology and the pathogeny of the disease are still conflicting and somewhat obscure. It is undoubtedly an inborn error of metabolism in which the characteristic features are pigmentation of the skin and the mucous membrane, hepatic cirrhosis and diabetes from which it probably got the nomenclature of 'bronzed diabetes'.

Dr. Sheldon has performed a big task in collecting data of 311 cases of the disease from the literature; he has analysed and then discussed the clinical and the pathological findings in a way which is indeed highly commendable. A complete picture of the disease has thus been presented to the readers, out of the materials obtained by him from the earliest times up to 1934. Such a complete summary of the records of hæmochromatosis is bound to be invaluable to anyone who wants to make further study of this particular or other allied subject.

Besides the carefully collected 600 references which the author has included in his bibliography, he has given a masterly exposition of the intricate subject of the mechanism of the pigmentation of the different organs and tissues with hæmosiderin in chapter VIII. and has offered a very reasonable hypothesis which may partially explain the phenomena of hæmochromatosis.

We have no hesitation in recommending the book to scholars and research workers interested in the subject of pigment and the mineral metabolism of the system.

J. P. B.

SURGICAL EMERGENCIES IN CHILDREN.—By H. G. Edwards, M.S. (Lond.), F.R.C.S. (Eng.). 1936. Baillière, Tindall and Cox, London. Pp. vii plus 274. Illustrated. Price, 12s. 6d.

MR. EDWARDS has added to the surgical literature a useful little book entitled 'Surgical Emergencies in Children'.

At first sight it may appear to some that surgical emergencies in children should receive the same sort of treatment as would be meted out to adults suffering from the same conditions.

Mr. Edwards declares that this is not so, and demonstrates in a clear manner his reasons for his opinion. He points out to the unwary that it is inadvisable to put a pin or a wire through the bones of a child, and therefore these methods of extension, so generally adopted in the adult, must in the case of children be replaced by plaster strapping. Appendicitis and intussusception, those two bugbears of childhood, rightly receive a great deal of attention; they are carefully dealt with and their complications described. We agree with the author that the giving of a spinal anæsthetic in cases of paralytic ileus, a form of treatment once so warmly advocated, is of little or no use. But we are surprised to note that he makes no mention of the use of acetylcholin in this condition, for the drug is useful, at any rate in the early stages of ileus.

Drainage of an empyema and the treatment of septicæmia are worthy of special mention.

The book is definitely good, it is well written, and it is obvious that Mr. Edwards is a keen observer. The volume should prove to be of great use, especially to the young surgeon at the outset of his career.

H. E. M.

MEDICAL RESEARCH COUNCIL. 'THE DETERMINATION OF IODINE IN BIOLOGICAL SUBSTANCES'.—By C. O. Harvey. Special Report Series, No. 201. 1935. Published by His Majesty's Stationery Office, London. Pp. 43. Price, 1s.

'It is well known that the element iodine plays a very important part in the metabolism of the body, and particularly in relation to the functions of the thyroid gland. The quantities involved are nevertheless exceedingly minute, and study of the subject is hampered by the difficulty of estimating them with accuracy in complex biological substances. The results of defective methods of estimating these minute quantities of iodine have indeed formed a lamentable chapter in medical science. It will be remembered that so long ago as 1850, Chatin began investigations into the distribution of iodine in foodstuffs and was led to formulate the hypothesis that simple goitre was related to deficiency of iodine—one of the earliest

instances of a deficiency disease, a type of ætiology now recognized as being so common. A Commission appointed by the French Academy of Science was unable to repeat his chemical findings and repudiated his hypothesis, with the result that the latter remained discredited until Baumann in 1895 discovered iodine in the thyroid gland. Chatin's hypothesis has since been completely vindicated by the work of McClelland in the United States and of von Fellenberg in Switzerland; moreover, the investigations in America of Marine and his colleagues have clearly shown the determining effect of the exogenous supply of iodine upon the morphology of the thyroid.

Even in recent years, however, difficulties and discrepancies have arisen in the course of investigations undertaken in different parts of the world to determine the relation of the iodine content of foodstuffs and water supply to the incidence of goitre in particular regions. This inquiry into the iodine content of soil and foods, in relation to the geographical distribution of simple goitre in Great Britain, yielded some suggestive indication, but the main conclusion was that further work on this and other aspects of the iodine problem could not profitably be undertaken until a more reliable method of chemical analysis for the purpose had been devised.

In these circumstances, the Council decided to promote the work which is now reported.

As the report will show, Mr. Harvey was successful in devising an improved and standardized method—based on Dr. W. H. Hurttley's modification of Professor Th. von Fellenberg's procedure—for determining small quantities of iodine in biological substances, such as blood, milk, and vegetable foods. Practical trial of it by Miss M. G. Crabtree, working for the Council at the Lister Institute laboratories at Elstree, and by Miss G. Mason, at the Rowett Research Institute, has shown that the method is capable of giving consistent results when parts of the same specimen are tested by independent analysis: their figures are incorporated in the report.

MEDICAL RESEARCH COUNCIL. 'REPORTS ON BIOLOGICAL STANDARDS. IV. THE STANDARDIZATION AND ESTIMATION OF VITAMIN A'.—Edited by E. Margaret Hume and Harriette Chick. Special Report Series, No. 202. 1935. Published by His Majesty's Stationery Office, London. Pp. 61. Price, 1s.

'DURING the last few years much has been done to make it possible to express vitamin potency in exact quantitative terms, by the improvement of methods of biological measurement and by the adoption of agreed standards. This meets the practical need for means of expressing the strength of the highly concentrated preparations of the various vitamins which are now available for therapeutic use, and the similar need in dietetics for means of measuring the vitamin content both of ordinary foods and of preparations in respect of which special claims are made by their manufacturers. The methods have also immediate value in introducing greater accuracy into fundamental research work in the field of nutrition.

The present international agreement on the subject of vitamin standards is the result of two conferences held in London, in 1931 and 1934, under the auspices of the Permanent Standards Commission of the Health Organization of the League of Nations. The decisions then taken had been made possible only by a great deal of preparatory research work, very much of which was done in this country. It is of a section of that work, concerned in particular with vitamin A, that this report gives an account.

At the first International Conference for the Standardization of Vitamins, in 1931, a provisional unit of vitamin A was established in terms of the biological activity of a sample of carotene. It was necessary to make this standard provisional, in the then imperfect state of knowledge, as it seemed clear that experience

would reveal possibilities of improvement. This was soon shown to be the case, for immediately after the conference several isomeric forms of carotene, including B-carotene, were isolated by various investigators; and, since it was evident that the standard carotene was a mixture, it at once seemed probable that a sample of a uniform substance could be substituted with advantage at some future date. A further point was that the crystalline form of the provisional standard had been found by some workers to be difficult to manipulate, making it desirable that any future standard should be issued in solution. The second International Conference, in 1934, accordingly adopted a solution of pure B-carotene as the permanent standard in terms of which units of vitamin A were in future to be expressed.

Much of the preparatory research work on the standardization of vitamin A, for both the International Conferences, was done by the members of a special sub-committee of the Accessory Food Factors Committee, appointed jointly by the Medical Research Council and the Lister Institute. In the course of this excellent team work all kinds of problems presented themselves, such as finding the best solvent for carotene and determining the conditions under which this substance remained stable in solution. In addition, completely new aspects of the subject arose, including the possibility of measuring vitamin A by a physical method, based on spectrophotometry, which necessitated a comparison of the spectrophotometric results with those obtained by biological methods. Thus researches were made which, although each separate item was possibly of minor importance, became in the mass of great interest to workers in the field. Some of the work had been published by the individuals concerned, but much remained unpublished: it was thought, therefore, that the collection and publication of all the investigations together would constitute an important record, very useful to other experts'.

MEDICAL RESEARCH COUNCIL. 'MEDICAL USES OF RADIUM. SUMMARY OF REPORTS FROM RESEARCH CENTRES FOR 1934'.—Special Report Series, No. 204. 1935. Published by His Majesty's Stationery Office, London. Pp. 45. Price, 1s.

'THIS report continues the accounts given in the twelve which have preceded it, of the research done with radium and radium emanation distributed by the Medical Research Council to selected centres in Great Britain and Ireland. On the clinical side, the report deals mainly with the treatment of various forms of cancer, but it contains also a brief section on the use of radium for some non-malignant conditions. In addition to describing work done during 1934, the report gives statistical data relating to the after-histories of patients treated in previous years. There is, further, a preliminary section dealing with purely experimental studies in the fundamental aspects of irradiation. The whole scheme of work is under the general supervision of the Radiology Committee, to whom the Council are indebted for the preparation of these reports. No account is included here of the research work in the treatment of cancer by "radium beam therapy" which the Council and other bodies are assisting under independent arrangements'.

MEDICAL RESEARCH COUNCIL. 'THE SOURCE OF INFECTION IN PUERPERAL FEVER DUE TO HÆMOLYTIC STREPTOCOCCI'.—By D. C. Colebrook. Special Report Series, No. 205. 1935. Published by His Majesty's Stationery Office, London. Pp. 99. Price, 1s. 6d.

'PUERPERAL SEPSIS, an infective condition due to the invasion of the body by harmful micro-organisms during childbirth, is not only a heavy cause of maternal mortality but also one of the great enigmas of medical science at the present time. On the one hand, medical

practitioners have for fifty years or more been living in an atmosphere permeated by teaching of the fundamental importance of antiseptics and asepsis. On the other hand, here is an infective state which still remains common in spite of greater precautions and better technical methods. These circumstances make the situation particularly challenging; and the challenge is not the less impressive because the condition occurs in what ought to be a normal physiological process, and often when there has in fact been little or no obstetrical interference. One thing is certain: a situation such as this must mean that knowledge of the problem of infection in general, and of this special aspect of the problem in particular, is imperfect, and that a solution can be attained only through better information about the factors at work.

It was in view of these considerations that the Medical Research Council were glad to give their support, in 1930, to the establishment of a "unit" of research in the subject at Queen Charlotte's Hospital, London, in the Bernhard Baron Memorial Research Laboratories attached to the new Isolation Block at Hammersmith. The funds which the Council were themselves able to provide for this purpose, in addition to the resources which the Hospital had available, were largely augmented by a generous subvention from the Rockefeller Foundation of New York, granted for a period of seven years. The particular inquiry here reported has also received some financial and other assistance from the Ministry of Health.

The present publication by Dr. Dora Colebrook is one of a number of valuable accounts describing the work done in the unit. Whereas it has long been known that the morbid agent responsible for most cases of puerperal sepsis is a streptococcus characterized by its ability to hæmolyse red blood corpuscles, it has been realized only in the last few years that the cocci having this property in common really comprise several groups and a number of sub-groups, of which only certain members are harmful to human beings. At first sight this would appear to complicate the problem from the point of view of the investigator, but in reality it does not: indeed the recognition of these different groups and sub-groups promises to throw much light upon the ætiological problems, not only of puerperal fever, but of a wide range of infections for which hæmolytic streptococci are wholly or in part responsible. In human pathology, that range includes scarlet fever, acute tonsillitis and epidemic sore throat, erysipelas, whitlow, impetigo, wound infections, "hospital sepsis", and perhaps acute rheumatism: in animal pathology, bovine mastitis, equine strangles, and other conditions'.

MEDICAL RESEARCH COUNCIL. 'REPORTS OF THE COMMITTEE UPON THE PHYSIOLOGY OF HEARING. III. THE LOCALIZATION OF SOUND'.—By H. E. O. James. Special Report Series, No. 207. 1936. Published by His Majesty's Stationery Office, London. Pp. 38. Price, 9d.

'THIS report is issued by the Medical Research Council on the recommendation of their Hearing Committee. It describes investigations which have supplemented the results of work published in an earlier report.

The research was directed to the solution of various problems of sound localization—the hearer's capacity to locate the origin of a sound reaching his ears. These questions included, especially, the effect of becoming accustomed (or "attuned") to a particular sound, continuous or repeated, upon the localization of other sounds heard immediately afterwards. This phenomenon had to be investigated as regards "attunement" to sounds heard with one ear and with both ears respectively. Study was also made of the part played in localization by differences in the intensity of the sound as received by the two ears.

The conclusions reached are of theoretical importance in the physiological and psychological study of the

phenomena of sound perception. They have also some interest from a practical standpoint, in an age when it is becoming more and more necessary to be able to perceive rapidly both the significance and the place of origin of many and varied noises, mechanically produced'.

BOOK RECEIVED.

WE have just received 'A Handbook of Tropical Therapeutics' by Brevet-Colonel Chopra, C.I.E., K.R.P., I.M.S. This appears to be a comprehensive and important publication; it contains 1730 pages. We hope to publish a review shortly.

Abstracts from Reports

THE REPORT ON THE WORKING OF HOSPITALS AND DISPENSARIES IN THE PUNJAB FOR THE TRIENNIUM 1932 TO 1934

OWING to the financial stringency, now fortunately drawing to a conclusion, the years 1932 to 1934 were necessarily of consolidation rather than advance. Schemes with which it was not practicable to proceed were those for the establishment of rural dispensaries throughout the province, the total completed out of the programme of 375 being 360, and the provincialization of hospitals and dispensaries, which by the end of 1930 had been effected in 45 places, since when only two other hospitals have been taken over by Government, viz, the Lady Aitchison Hospital, Lahore, in 1932, and the Civil Hospital, Rohtak, in 1934, the Government's hands being forced by the inability of the authorities in charge of them to provide funds for their maintenance. As soon as finances permit, the Government will proceed with its programme of provincializing 66 more district and tahsil headquarters hospitals and dispensaries.

In spite, however, of expenditure having had to be cut to the bone, there were a number of important measures, for which funds could be found, the most notable being the provision of facilities for radium treatment, and also a considerable increase in the number of beds at the Mayo Hospital, Lahore, the inauguration of the de Montmorency College of Dentistry and the completion of the Lady Willingdon (Maternity) Hospital. The very large number of patients treated at the dental hospital supplies ample clinical material for the students. The public demand, which existed for a Government maternity hospital, is demonstrated by the statistics for the Lady Willingdon Hospital, to which Indian women increasingly resort, and which also fulfils the important function of providing clinical material for the training of students at the King Edward Medical College in practical midwifery and gynaecology, and thus saves Government the expense formerly incurred in sending students for this purpose to Madras.

The Government is satisfied from the report that the chief Government hospitals, viz, the Mayo and Albert Victor Hospitals, Lahore, the Civil Hospital, Amritsar, the Lady Willingdon Hospital, Lahore, and the Lady Aitchison Hospital, Lahore, continued to be satisfactorily administered and to cater for the needs of an increasing number of patients. Until the latter hospital was provincialized, there was a danger of its coming to an untimely end. The necessity for its continued existence was great, as this is the only hospital in Lahore (and one of very few in the province) where medical attendance for women is provided entirely by qualified lady doctors.

The Government is gratified to observe that steady progress continues to be made with the provision of medical aid for women. The extent to which women are availing themselves of it is shown by the number of women patients at hospitals and dispensaries, which rose from 3,140,271 outpatients and 70,550 inpatients in 1933 to 3,249,818 outpatients and 76,537 inpatients in 1934. These figures refer to women patients treated at ordinary hospitals, as well as at women's hospitals or wards where lady doctors are available. Of the latter there are now 85 in all, 42 hospitals and 43 wards for women, under the charge of lady doctors; and of

these 85 institutions, 25 are maintained by Government, 32 by local bodies and 28 by missionary societies.

At the same time, gratifying progress has been made with medical education for women. The chief training centres are the Lady Hardinge Medical College, Delhi (for which the Punjab Government may nominate 7 students), the Punjab Medical School for Women, Ludhiana, to which is affiliated the Memorial Hospital mentioned above, and also the King Edward Medical College, Lahore, and the Medical School, Amritsar; in both of the last a system of co-education prevails, 10 seats in the former institution and 15 in the latter having, since 1929 and 1932 respectively, been reserved for lady students. In the year 1934 11 such students qualified for the M.B., B.S. degree of the Punjab university and 22 for the L.S.M.F. Diploma of the Punjab State Medical Faculty. Though the supply of lady doctors is still far short of requirements, it is now clear that ultimately the supply will be commensurate with the demand. It is also reassuring to learn that the number of qualified midwives shows a steady increase, the number of women who qualified in 1934 being 50 for the Diploma in Midwifery, 43 for the Nurse Dais Certificates, and 290 for the Indigenous Dais Certificates of the Punjab Central Midwives Board.

The increasing seriousness of the leprosy problem is becoming more evident, as a result of intensive surveys which have been made under the auspices of the Punjab Branch of the British Empire Leprosy Relief Association. This society employs a provincial leprosy officer, who is at present conducting a census of lepers throughout the province, and who has arranged for the establishment of clinics in various districts, and also for the training of doctors in anti-leprosy treatment. The 5 leper homes of the Punjab are maintained by missionary societies and are under the care of fully trained medical officers. At the end of the period under report, however, the American Presbyterian Mission expressed their inability to manage the Ambala Leper Home, which has been taken over by the Punjab Branch of the British Empire Relief Association. The Government makes a grant-in-aid towards the maintenance of the five leper homes, on a *per capita* basis for patients up to a fixed number. Accommodation, however, is becoming inadequate, partly as the result of 'burnt out', i.e., non-infectious cases remaining on at the homes, and partly owing to the number of lepers from places outside the Punjab. The Government considered the question of asking other administrations to contribute towards such lepers, but, as Punjab lepers are also accommodated in leper homes outside the Punjab, this was found to be impracticable. Government, however, is determined to organize a drive against leprosy, and has under consideration proposals for provincializing the post of leprosy officer, and for making special arrangements for 'burnt out' cases.

Another direction in which great progress was made during the triennium was in that of anti-rabic treatment. A very large number of patients attended the provincial bacteriological laboratory at Lahore, 4,760 being treated in 1933 and 4,392 in 1934, no death among all these cases being reported. The decrease in 1934 was due to the establishment of anti-rabic centres in 1934 at all district headquarters hospitals, doctors having been specially trained for the purpose; and in

the last five months of the year over a thousand patients were treated at such centres.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF BURMA FOR THE YEAR 1934

Cholera.—In his annual report for 1932, the Director of Public Health referring to the low figures for cholera in that year stated: 'The conditions favouring an outbreak are still generally present, and the influences which have limited the spread of this fatal disease may be removed at any moment'. The reduced incidence was unfortunately shortlived. It lasted throughout 1933, but in the autumn of 1934 the disease reappeared in epidemic form and continued with increasing severity up to the end of the year. Its appearance at this season of the year was quite unusual; a study of the seasonal distribution of cholera in Burma shows that its highest incidence has usually been in the months of April and May. Past epidemics have usually made their appearance in the spring.

Anti-cholera measures.—The public health staff in the affected districts was reinforced at an early date. Inoculation with anti-cholera vaccine was offered freely from the beginning. The public was sceptical at first, but intensive propaganda brought a better response. The villagers then began to recognize that the inoculated persons remained unattacked by the disease, and there were some dramatic instances of the only uninoculated member in a family dying of the disease while the rest of the family remained unattacked. The news of such happenings spread and helped to popularize inoculation and, as a result, a total of 96,224 persons had been inoculated by the 31st of December.

To purify the water in the creeks was of course out of the question, but wells and tanks were treated to as large an extent as possible with bleaching powder. The village conditions did not permit of segregation to any appreciable degree.

Smallpox.—The incidence of this disease was slightly in excess of the previous year's rate and of the five-year mean. As in 1933, the infection was widespread, only two districts being entirely free from the disease. The seasonal distribution of most of the cases was, as usual, from March to May, the lowest incidence being in October. More than half the cases (67.08 per cent) were among people over 10 years of age. It is reasonable to believe that many of these were vaccinated in childhood, and the figure shows how necessary it is in this province to get people revaccinated in order to keep up immunity against the disease.

Plague.—The rate is 0.11 higher than last year and 0.05 more than the five-year mean. As usual the seaboard districts remained free. The one death that occurred in Mergui district was imported from Moulmein by steamer, and was detected when the patient reached Victoria Point. Pyapon and Lower Chindwin districts reported no case. The remaining districts were all infected. The seasonal incidence was normal, the majority of cases occurring between December and March.

Anti-plague measures. (a) *Rat destruction.*—The total number of rats killed by trapping and smoking during the year was 802,185 compared with 724,165 in 1933. As in previous years, the large majority, viz, 734,689, were reported as killed in the Rangoon Corporation area.

It has long been felt that trapping and smoking of rats are not likely to bring about any appreciable reduction in the rat population of the province and in the incidence of plague. The success gained in the Madras Presidency, where the fumigation of rat burrows with cyanogas seemed to bring about a definite reduction in plague in Cumbum, encouraged this department to introduce this method of rat destruction in July 1934. A start was made in Mandalay, and the early success met with in that town resulted in a circular being issued to all health officers, asking that the cyanogas method of rat and rat-flea destruction should

be taken up. The response has been satisfactory, in so much that 44 municipalities and 19 district councils purchased the necessary apparatus with a supply of cyanogas. Municipal and rural health staff have been trained by officers of the public health department. This all took time and the use of cyanogas up to December 1934 cannot be described as general. In Mandalay, however, a well-organized campaign was kept up and is continuing throughout 1935, in the hope that the expected epidemic in the plague season of 1935-36 will be averted. By the end of 1934, four gangs were employed in this work in the plague-infected areas of Mandalay, and they were able to treat 43,500 rat holes in 5,920 premises. The co-operation of the inhabitants has been excellent and any opposition negligible.

Inoculation.—The total number of inoculations performed during the year was 103,667, an increase of 32,743 over the previous year. Of this year's total, 43,632 were done in the rural areas and 60,035 in towns. The response of the public to inoculation is improving, and its value as a protection against the disease is being recognized in a steadily increasing way.

Fevers.—There was an increase of 0.69 over 1933 and 0.89 over the five-year mean. Under the general heading 'fevers', 37.74 per cent of the total deaths in the province were recorded. A large proportion of these 'fevers' is undoubtedly malaria, and this is borne out by the fact that the highest number of deaths from 'fevers' was recorded in December, in which month the highest number of deaths from malaria was also reported.

Enteric fever.—The total number of deaths recorded is 267, which, it is considered, does not represent the true incidence of this type of fever. Bacteriological diagnosis is only resorted to by private practitioners in a small proportion of the cases of fever, and it is believed that a number of enteric infections are missed. The disease is notifiable in towns. Of the cases reported from Mandalay, 76 per cent had a fatal ending, which high figure suggests that many non-fatal cases probably went unreported.

Respiratory diseases.—This figure is 0.07 higher than last year and 0.06 over the five-year mean. The months of April to June show the lowest incidence for this group of diseases. Deaths were scattered fairly evenly throughout the rest of the year, with the highest figures in August and December. The higher mortality amongst males in the proportion of 135 : 100 was practically the same as in the previous year.

Beri-beri.—Only inadequate figures are available for this disease in the rural areas. Its prevalence is recognized in the Upper Chindwin, Mergui, Toungoo and Kyaukpyu district. In the Upper Chindwin and Toungoo, it is commonest amongst the mahouts of the timber camps. Its incidence is generally associated with cold and damp conditions, and the district health officer, Upper Chindwin, states that as soon as the cases are moved out of the camps and brought to Mawlaik hospital, they make a rapid recovery. The cold and damp conditions are probably only a contributory cause, and as far as can be ascertained the cases are due to vitamin B deficiency in deteriorated rice. In Mergui, the disease is practically confined to the Telugu coolies, who are reported to live on a low scale of diet. Few cases are noticed among the Burmans. In Kyaukpyu, it occurs in the Cheduba Island and to a lesser extent in Ramree Island. In the Southern Shan States, a few cases occurred in Loimwe and Kengtung towards the end of the monsoon, and are said to have been of a sporadic nature.

In the towns the rate shows an increase of 0.02 compared with last year but a decrease of 0.03 compared with the five-year mean. In Mergui, the Telugu coolies are said to have been the main sufferers, and in Moulmein this was also the case. In Syriam, 29 cases were admitted to the hospital of whom 7 died. Of these 16 were imported and 13 indigenous. Almost all were coolies who were unemployed, and in consequence ill-fed and undernourished.

Goitre.—The prevalence of this disease is mentioned in the annual reports from the Northern Shan States, Mogok and Toungoo district. In the Northern Shan States, it is found amongst the Palaungs and the Kachins living at comparatively high altitudes.

Yaws.—This disease is very prevalent in Mergui and Tavoy districts. In Mergui it is said to have been confined to Salons, Malayans and Siamese, but it is now spreading among Burmans and Karens who live in the interior of the district. It is regrettable that financial stringency made it impossible to continue the co-operation between the Mergui district council and the Deputy Commissioner's local fund, Tavoy, which, in the previous year, had enabled an effective treatment campaign to be carried out in the upper reaches of the Tenasserim river. In that year a sub-assistant surgeon had transversed the affected area and had treated over 500 cases. Similarly in Mandalay district, where a survey of yaws had been carried out, the district council was unable to provide funds for treatment. In the Upper Chindwin district, yaws is common in the old Maingkaing and Mingin townships, which are far away from hospital treatment. In Mogok subdivision, the villages of Letpangon, Sezingon and Zigon were infected, but the medical authorities found it difficult to induce the people to come for treatment. In Sagaing and Katha districts, in the Chin Hills and in the Lower Chindwin district, the disease is also reported to be fairly common.

Leprosy.—No new leprosy survey was carried out during the year, as it was considered better policy to consolidate the work in the Minbu and Meiktila districts which had been already surveyed. A special officer was stationed in each district for this purpose. The colony which had been opened in Minbu in December 1933 progressed on satisfactory lines, and at the end of the year 34 lepers were residing in it. Its initial expenses were defrayed by a grant of Rs. 500 from the Burma Branch of the British Empire Leprosy Relief Association, Rs. 350 from the district council, Rs. 100 from the municipality and Rs. 50 from the Deputy Commissioner's local fund. There is a demand for increased accommodation in the colony, and its year's work can certainly be regarded as satisfactory. There are two classes of patients in the colony, private and public. The private patients are given only free treatment and make their own arrangements for food. The expenditure on the public patients is met entirely from the special leprosy fund. The clinics in the towns in this district did not meet with the same success. The distances that people had to travel to get to the clinic made it difficult to increase the numbers.

In Meiktila district there were clinics in Meiktila itself, in Mahlaing, Wundwin and Thazi, and the special leprosy officer's work resulted in satisfactory attendances. The leprosy problem in this district is a very serious one. The figure given in the 1931 census for lepers in this area is 1.31 per 1,000, but a survey of 19,249 people showed that the true incidence is 16.57 per 1,000. If this survey ratio is taken as representative of the whole district, which has a population of 309,999, it means that there are over 5,000 lepers in Meiktila district alone. The need for a leper colony is very great and for that reason a local committee consisting of the leading persons in the district was formed in September 1934 to raise funds and to establish a colony. It is disappointing to record that up to now the difficulties of securing a site have not been solved. Suitable sites are available near Meiktila, but the prejudice, organized or otherwise, of the local villagers against the establishment of a leper colony near them has held matters up. The Burma Branch of the British Empire Leprosy Relief Association is ready to help the colony with a grant, and in fact has already handed over some money for the sinking of a well.

In Monywa, the excellent record of the leper colony, which was established there in 1927, has been maintained and at the end of the year there were 60 resident patients. In Kengtung in the Southern Shan States,

a colony is run by a Roman Catholic mission and at the end of the year 82 patients were living in it.

Veneral disease.—The venereal disease statistics of this department, relating only as they do to deaths, afford no criterion of the incidence of venereal disease in the province. Widely varying estimates have been made as to the degree to which it prevails. Hospital statistics afford little clue, as it is believed that only a small percentage seek treatment there, a large number being treated by quacks. The figures obtained from the post-mortem room of the Rangoon General Hospital show that out of 791 cases examined in 1934, 166 or 21 per cent showed pathological signs of syphilis. The superintendent of the Mandalay hospital sent regularly, from September 1933 onwards, specimens of placental blood taken in the labour room from apparently healthy patients. These were subjected to the Kahn test and 21.8 per cent were found positive. Similar examinations of placental blood from the Dufferin Hospital, Rangoon, revealed 3.1 per cent as positive to the Wassermann test.

Rabies.—The death rate was 0.02 which is the same as for both the previous year and the five-year mean. The number of persons treated for rabies during the year in all the treatment centres was 3,803, and the daily average attendance for treatment of rabies at the Pasteur Institute, Rangoon, was 74, compared with 64 in the previous year.

During the year by-laws for the keeping of dogs and the destruction of stray dogs within municipal limits were passed by the Henzada, Pyinmana, Kyonpyaw and Bhamo municipalities.

Conservancy.—The campaign to introduce bored-hole latrines in the rural areas continued throughout the year. In Akyab, Henzada, Myaungmya and Pyapon districts this type of latrine was installed in varying numbers. Where the latrine was properly cared for it has been successful, but in a number of cases its efficiency has been destroyed through the negligence of the inhabitants. From reading the annual reports from districts in 1934, the impression is gained that there is some slight movement in the state of apathy that has characterized the villager regarding his environment. There is a long road to travel before a really appreciable improvement can be brought about. The tying of cattle under houses, the non-removal of rubbish and crowding, the lack of proper latrines are big obstacles to obtaining anything like clean villages. The youths improvement society, a new body of young men pledged to raise the standard of rural sanitation, has made a start by visiting villages and preaching the benefits of good sanitation, in some cases giving demonstrations of the benefit of the bored-hole latrine. If the society continues its work on the right lines, it is reasonable to hope for an appreciable effect in the areas in which they work.

Rural Health Unit, Hlegu.—The health unit, in its fifth year of existence, had a very satisfactory record of work. Each year since the unit was started in 1930 has witnessed the introduction of some additional type of activity and improvement, and the standard of public health administration which has now been reached in the Hlegu township is a satisfactory one. The early period of scepticism and doubt on the part of the inhabitants has been left behind, and the unit is now firmly established, conferring real benefit on the people whom it serves and standing for the rest of the province as an example of progressive rural health work carried out on sound lines.

The unit has met with exceptional success in the matter of elucidating accurate vital statistics, which are necessary if the magnitude of the problems and the results of remediable measures are to be properly assessed. The efficient registration introduced by the unit has revealed the rather startling fact that the ratios of births and deaths in the township, for the five years previous to the inception of the unit, were in error to the extent of 122.53 per cent in the case of births, and 76.18 per cent in the case of deaths. The Hlegu figures can now be considered accurate, and

inadequate information received regarding patients treated at the centres.

Anti-rabic treatment is now so well established and, except for rare cases, apparently so free from risk of accident, that it is open to question whether, save as a means of collecting accurate data regarding the treatment, the *raison d'être* of authorized treatment centres has not largely disappeared. The compilation of reliable statistics relating to anti-rabic treatment is, however, undoubtedly of great importance, as part of the constant work which is going on all over the world towards improved methods of treatment, and it is particularly from the institutes in India, where such large numbers of cases are dealt with, that valuable information can be obtained.

A memorandum of instructions regarding anti-rabic treatment is shortly to be issued and it is hoped that this will help medical officers in charge of treatment centres in dealing with persons applying to them for anti-rabic treatment and in recording the necessary data, but no written instructions can replace practical training.

It is therefore strongly recommended that Government should take the necessary steps to ensure that all medical officers in charge of authorized treatment centres have received sufficient training in anti-rabic methods to enable them to carry out satisfactorily the special duties of their charge.

In default of such training it is the writer's opinion that the policy of restricting anti-rabic treatment to authorized centres might well be reconsidered and the collection of data of doubtful value be subordinated to the primary need for securing the early treatment of every person at risk.

Bacteriophage.—The demand for this product has steadily risen since its preparation was undertaken at this institute. During 1934, 871,316 doses were issued, which is 164,152 doses more than in 1933. Of this amount 652,960 doses, or 222,080 more than last year, were supplied free by Government to the bacteriophage controlled areas of Nowgong and Habiganj: 41,312 doses were supplied to other Government institutions in the province, 87,920 to tea gardens, 1,342 to missions, 3,712 to railways, 35,510 to other private institutions, 832 to municipalities, 29,424 to local boards and 18,304 to other Governments.

The production of bacteriophage for therapeutic use is very carefully controlled at every stage in its preparation. Freshly isolated bacteriophages are used for every brew and each brew is carefully analysed before issue. The brews contain at least 8 to 10 types of cholera bacteriophage of high potency and bacteriophages active against most of the known strains of dysentery bacillus.

A complete reorganization of the malaria section was made with a view to the better co-ordination of malaria surveys, of the routine examinations of specimens connected therewith and of the researches in hand.

The staff of the malaria section numbered 58, of which 17 are qualified medical men with special training in malariology; 9 being sub-assistant surgeons, public health department, deputed for a full year's training in the laboratory and in the field.

One member of the staff took the course in malariology at Karnal during the year.

Owing to the large number of surveys on hand and the necessity for inspection hours by the research officer and senior members of the staff, the usual cold weather training class could not be held this financial year.

A study of the periodicity of malaria factors in Assam was undertaken. From dissections of mosquitoes this year we have still further confirmed previous work showing *A. minimus* to be the significant vector in the Brahmaputra Valley of Assam. We have determined that there are areas of non-endemicity and areas of varying degrees of endemicity in which the transition of intensity from a low to a high degree may be either abrupt or gradual. We have studied the reasons for this differing intensity and have shown that the differences in water conditions are solely

responsible. From these studies we have determined that under certain conditions where there is no significant extension of breeding to other than perennial streams, malaria may be reduced by the introduction of cold weather and pre-monsoon antilarval activities and that, under these conditions, antilarval work undertaken in the monsoon season is not justified and is uneconomical. In such areas, which we suspect to be the predominating type in Assam, the cost of antilarval operations can be reduced enormously by these findings. In other areas where breeding is carried over from the perennial streams to *bhils*, swamps and clear running drains during the monsoon season, antilarval activities will have to be continued for a longer period and by different methods. Such areas are in the minority.

Bacteriophage enquiry under the Indian Research Fund Association

On the whole, the cholera history of Assam during the year 1934, analysed as it necessarily has been on somewhat speculative grounds, cannot be said to lead to any definite conclusions either for or against the value of bacteriophage when used alone on a large scale as a preventive of cholera, and the whole question, so far as this year's results go, must still be regarded as *sub judice*.

[*Basic research.*—A great deal of work under this heading has been carried out and this section of the report will be found of considerable interest to specialists.]

ANNUAL REPORT OF THE UNION MISSION TUBERCULOSIS SANATORIUM, AROGYA-VARAM, NEAR MADANAPALLE, SOUTH INDIA, 1934-35

On 1st October, 1934, the number of patients remaining from the previous year was 232. During the year, 391 patients were admitted and 402 patients discharged, leaving on 30th September, 1935, 221 patients. The total number of patients treated during the year has been 623. The daily average number of patients treated has been 228.34 for the whole year. The lowest number of patients on any single day was 218 in the months of January and July 1935; the highest number was 240 in the month of May 1935. The number of beds available during the year varied from 229 in the first half to 232 in the latter half. During most of the year there has been a long waiting list for the general wards and also for the special wards. In September the number of patients on the waiting list for the general wards for men only was 70.
